" vegetable do.	346.0
" mixed do.	500.5

Our own experiments, with the same specific gravities as before, give:—

Sp. gr.	Ounces.	Urea in 24 hours. Grains.
1023	29	205.62
1017	51	218.28
1021	35	248.50
1018	55	280.53
1032	31	389.35
General mean		268.78

These numbers, intermediate between those of Becquerel and Lecanu, are perhaps not far from the truth, and may be regarded as the limits of health, as far as relates to excretions of urea in the 24 hours, in a person living in an ordinary manner. The above numbers being taken as the average for males; females may be considered as secreting as near as possible, in the 24 hours, 2 per cent. less urea.

[To be continued.]

Medical Trials and Inquests.

SUPREME JUDICIAL COURT, BOSTON.

March 19, 1850.

REPORT OF THE TRIAL OF DR. WEBSTER FOR THE MURDER OF DR. PARKMAN.

*Before Chief Justice Shaw and Justices
Wilde, Dewey, and Metcalf.*

[SOME delay has taken place in the publication of an abstract of this remarkable trial, owing to our space having been much occupied, and to the fact that we considered it necessary to wait for the publication of the details in an authentic form. The Report now before us, prepared by Dr. J. W. Stone, is a most elaborate account of the proceedings at this trial. It consists of 314 closely-printed octavo pages. We shall confine ourselves chiefly to an outline of the facts, with a transcript of the medical evidence. To the medical jurist the case presents numerous interesting questions relating to the identity of the dead and the cause of death;—and to all readers, the marvellous nature of cumulative circumstantial evidence, with the multiplication of the proofs of guilt, even

where an attempt was made to destroy these proofs by a criminal use of scientific knowledge. Dr. Webster had attained a high position as a scientific chemist in his own country, and had also acquired some repute on this side of the Atlantic. In our forty-third volume, 1849, page 894, we published a remarkable case of murder by poison, in which he was himself the means of leading to the detection of the crime fourteen years after its perpetration. The social position of the criminal, and his standing as a scientific man, give a painful and awful interest to these proceedings, which, chiefly by circumstantial evidence, clearly brought home to him the perpetration of a crime terrible for its atrocity, and for the art with which he attempted to conceal it. These considerations render it a duty to transfer to our pages the principal details of this case: as no doubt they will not only prove interesting to present readers, but will be sought after by future inquirers.]

The prisoner, JOHN W. WEBSTER, was charged with the murder of Dr. GEORGE PARKMAN, of Boston, on the 23d November, 1849. There were several counts in the indictment, laying the mode of death as having been produced by wounds or personal injuries. He pleaded *Not Guilty*.

From the statement of the Attorney-General, for the prosecution, it appeared that Dr. George Parkman, a well-known and highly respectable citizen of Boston, was living, in good health and cheerful spirits, on the morning of Friday, the 23d day of November last; that he was engaged in his usual occupations on that day, up to fifteen minutes before two o'clock, at which time he was last seen alive, about entering the medical building in Grove Street. He did not return to his dinner on that day; a fact which, on account of the habits of Dr. Parkman, was of itself calculated to excite some uneasiness in his family. It appeared that Dr. Parkman left some lettuce in a shop near the Medical College, with the intention of returning to take it, and thence to carry it home. At that shop he made certain purchases. He did not return. The lettuce remained there. After he went to the Medical College, although he was expected to return in a few minutes to take it, he did not return, and he did not return to his home. On the 30th of November, the Friday after his disappearance, in the vault of a privy connected with the defendant's laboratory at the Medical College, were found parts of a body answering to the description of Dr. Parkman. They consisted of a pelvis (the hip bones), the right thigh (from the hip to the

knee), the left leg (from the knee to the ankle); and with them were found certain towels with the initial of the prisoner, and similar to those used by him in his laboratory. On that day, Friday, and the next day, Saturday, were also found in the furnace of Dr. Webster's laboratory, fused in with the slag and cinders, as the evidence will show, and which is important in one view of this case—fused in indiscriminately with the slag, the cinders, the residuum of the coal—a great number of bones, and certain blocks of mineral teeth. Certain quantities of gold which had melted were also found, and other substances, which will be disclosed by the testimony. On Saturday morning there was found a tea-chest, containing, imbedded in a quantity of tan, and covered with minerals, the thorax or entire trunk of a human body, the left thigh, from the hip to the knee, and a hunting knife of a peculiar character; and around the bone of the thigh, a piece of twine or marline, which will be produced—a specimen of which will be produced here, with other specimens found in his laboratory. These parts were subjected to the examination of competent medical and scientific men. They were put in apposition,—I speak now of the parts found in the privy and in the tea-chest, independently of the bones found in the furnace,—they were put in apposition, and found to resemble, in every particular, the body of Dr. Parkman, or such portion of the body as these parts corresponded to; and, in no single particular, dissimilar to the body of Dr. Parkman. There were missing from this human body, when placed in apposition, the head, the arms, hands of course, both feet, and the right leg from the knee to the ankle. The evidence will show that they belonged to a person about the age of Dr. Parkman. He was about 60 years of age. The evidence will also show that the form was peculiar, as his was peculiar. It will be testified by the witnesses, that the height, 5 feet 10½ inches, corresponded precisely to the height of Dr. Parkman, taking, as the witnesses will explain, the average length for these missing parts—the head from the neck, and the foot from the ankle. It is not necessary for me to detain you by details. The witnesses will explain how they reach this result, to which they come, that the height of the person to whom these parts belong was 5 feet 10½ inches. And we shall show, by the passport of Dr. Parkman, that he was of precisely that height. The evidence will also prove that he was of a peculiar form and shape, and that this body was also of that peculiar form and shape; that the hair indicated something similar, and in no respect dissi-

sailor, to that of Dr. Parkman. But then, gentlemen, we shall put into this case evidence which, upon this point, I shall leave you to judge of, and to take the proper estimate upon. For I am not here to comment upon it, but merely to state to you a general outline of what it is. Of the bones found in this furnace, not a fragment was found which duplicates any one found in the vault or the tea-chest, but every particle of bone belonged to some part of a human body not found in that vault and tea-chest; showing that unless by a miracle they agreed, the bones found in the furnace, the parts found in the tea-chest, and the parts found in the vault, all constituted portions of one human body. There will also be some evidence which will perhaps indicate to your minds a probability at least, if not a conviction, that some of the bones found in the furnace were fractured before they had ever been subjected to the action of fire—the bones of the cranium (of the head). I say that there may be some evidence of this, indicating that before the bones were subjected to the action of fire, those bones had been fractured.

Then, gentlemen, you will have placed for your inspection a block of mineral teeth, which was found in that furnace, and found so near the bottom of the furnace that it took the current of cold air,—found resting upon the grate, a fact of some significance,—a block of mineral teeth, which will be testified to by two gentlemen, accomplished dentists, to be the teeth of Dr. Parkman, made for him in 1846, upon an occasion which Dr. Keep distinctly recollects, recognizing his own work, and beyond that giving you the grounds upon which he feels the confidence that he will express in his testimony; a confidence so strong, from his recollection of the work itself, and the formation of these teeth, the peculiarities of their formation, and other facts, that if he had seen them in Africa, or beyond the sea, he should have known them to be the teeth which he made for Dr. George Parkman, in the autumn of 1846. There were other portions of mineral teeth found, which will go to aid you in your judgment of the reliability of the testimony of Dr. Keep, but which are not so characteristic as the block of which I speak. It will be shown that Dr. Keep has in his possession, and can produce now, a mould of the entire jaw of Dr. Parkman, taken at the time he made this block of mineral teeth. You will see, by that mould, which will be testified to you by Dr. Keep, that it is a mould which showed the peculiar conformation of Dr. Parkman's jaw,—a peculiarity so great, that you could not find, through any ex-

prise of nature, another precisely like it. It will appear from the evidence, that these mineral teeth must have been cast into that furnace in connection with the head. That will be made perfectly clear and apparent to you, upon the evidence, found in connection, as they are, with certain portions of the bones, which will be explained to you by another medical, anatomical, and scientific witness. Beyond this, you will have exhibited to you, from among the bones, the bones of the right lower jaw, found in that furnace, in fragments, in portions, there broken and with serrated edges, put together to show that they belonged to one and the same jaw; and the conformation of that jaw, when thus put together, you will find precisely like that taken in the mould in 1846, by Dr. Keep. This will be the nature of the evidence to satisfy you that Dr. Parkman came to his death as charged in that indictment, and in connection with the Medical College.

There are one or two points, before proceeding to the other evidence, which I shall offer, to which it may be proper, in this connection, to advert. The thorax, which I have spoken of as having been found in the tea-chest, exhibits a perforation, upon which there will be evidence laid before you to show that it was a wound which penetrated between the ribs, taking off a portion of the membrane which covers one of the ribs, and entering the region of the heart. It will also appear to you that to these remains there have been chemical applications made of strong alkalis, which, upon a chemical analysis, is found to be demonstrated by an accomplished chemist, who will be here to state the result of his examination. The inference to be drawn from these facts cannot now be properly presented. It will be demonstrated to you, that these remains are not the remains of a subject in the Medical College, for two reasons: one, that there was no injection in the veins of any preservative fluid, which is the invariable custom there; and, secondly, that all the subjects are accounted for, independently of this, by Dr. Ainsworth, who keeps an accurate record of them.

The evidence will show you that the remains were separated (I was about to say mutilated, but separated, perhaps, will be a better word) by some person having an amount of anatomical skill, though evidently not dissected for anatomical purposes. There are various other facts, in connection with these remains, which I will not detain you to recite: you will appreciate them as they come from the witnesses. This is the nature of the evidence upon which the Government say that these were the remains of Dr. Parkman, and

that he must, upon this state of facts, have come to a violent death.

[We do not propose to enter into the moral evidence, supplying a motive, as it was alleged, for the perpetration of the murder. It may suffice to state, that Dr. Parkman had lent Dr. Webster a considerable sum of money, and had vainly endeavoured to procure payment. It appears that the prisoner had called at Dr. Parkman's house, and had made an appointment for him to come to the Medical College on the afternoon of the day on which Dr. Parkman disappeared, in order that the account between them might be settled. We subjoin the medical report on the examination of the remains found in the College, concealed in Dr. Webster's laboratory.]

Report of the Medical Committee on the Investigation of the Remains.

Drs. Winslow Lewis, junior, George H. Gay, and James W. Stone, being severally sworn, on oath depose as follows:—

Having been directed to make a post-mortem examination, at the Boston Medical College, in North Grove Street, attended to that duty December 2d, 1849, at ten o'clock A.M., and examined five portions of a human subject, viz.: a thorax, a pelvis, two thighs, and a left leg. The thorax and left thigh were discoloured, apparently with tan and some caustic substance. The three remaining ones were white, fair, and appeared as if soaked in water. The cartilage on the head of the left thigh-bone was coloured black. The following is a description of the five portions separately:—

I. *Remains of Thorax*, and parts attached to it, which consisted of all the bones except the sternum. Fracture of the fifth right rib, apparently recent, and about four inches from division between ribs and sternum. Both clavicles and scapulae present; clavicles large. Both lungs present, but collapsed. Left lung had pleural adhesions. Structure of both lungs apparently healthy. Anterior thoracic muscles cut up from the ribs, about six inches from the centre, on each side, and with the skin thrown on one side. Posterior portion of integuments, from the scapula to the left lumbar vertebrae, of a dark mahogany colour, and hardened. Remaining portion of integuments generally of a natural appearance, except a little greenness under the right axilla, probably from commencing decomposition, and some blueness under the left axilla, leaving the skin soft and easily broken, through artificial action exerted upon the hair and skin, as far forward as the section in the median line. An opening, slightly ragged, about an inch and a half in length, under the left nipple,

between the sixth and seventh ribs, extending into the cavity of the chest. Remains of thoracic aorta and thoracic oesophagus present. Heart and diaphragm wanting. Trachea divided through the cricoid cartilage. Spleen contracted, externally granulated, and internally red. Left kidney in its natural position, and contracted. No liver, right kidney, pancreas, stomach, or intestines.

N.B. The right kidney, much contracted and discoloured, was discovered on the next day, and given to us.

Sixteen vertebrae present, consisting of three lumbar, twelve dorsal, and the greater portion of the seventh cervical, which appeared to have been sawn through the upper part. Small quantity of long grayish hair on the front of the chest. Some stained dark grayish hair on the back. Periosteum removed from the front part of several left ribs. Both arms severed in a very irregular and unscientific manner.

II. *Pelvic portion* consisted of the bones of the pelvis, two of the inferior lumbar vertebrae, all the integuments, muscles, organs of generation, and the pelvic viscera generally. All of the intestines remaining was about six inches of the rectum, through the anterior and external portions of which a section had been made, and the mucous coat separated from it four or five inches throughout the whole circumference, but not cut off at the lower end. Hair upon this portion of a sandy gray. Both thighs severed from it in a very irregular manner. Integuments divided down to the pubis in the median line. On placing the pelvic portion in apposition with the thoracic, the third and fourth lumbar vertebrae corresponded precisely. The spinous process of the third lumbar vertebra, with a portion of the transverse processes of the same, was absent from the thoracic portion, but was found attached to the fourth lumbar vertebra, which was on the pelvic portion.

III. *Right Thigh*, on being placed in apposition with the pelvic portion, the bones, muscles, and skin corresponded perfectly. Good muscular development, with but little of fatty matter. Patella attached. Some ossification of femoral artery.

IV. *Left Thigh* had a string about two and a half feet long, tied round just above the condyle, leaving loose ends. Patella attached. On being placed in apposition with the pelvis, the bones corresponded, but some portions of the skin and flesh appeared to have been removed, or contracted from artificial means. On the anterior surface of the thigh, and somewhat on other parts, there were appearances of the action of fire, or some caustic matter.

V. *Left Leg* of natural appearance, fair size, and on being placed in apposition

with the left thigh; the articulation corresponding.

Measurements.

	Inches.
Thoracic portion, length . . .	17½
" below axilla, circumference, 30 inches.	
Pelvic portion, length . . .	9½
" circumference below crest of ileum, 30½ inches.	
Both thighs (of the same length) . . .	18
" circumference of largest part of each, 18½ inches.	
Left leg, length to the outer malleolus . . .	16
" " circum. of largest part, 12½ in.	

Total . . .	61
Deduct distance from bottom of pelvis to top of acetabulum . . .	3½
	57½

All the parts being placed in apposition, the distance from the top of seventh cervical vertebra to the outer malleolus . . .	57½
---	-----

Difference . . . ½

Total length of parts discovered . . .	57½
Distance from sole of foot to the outer malleolus on another subject . . .	3
Distance from top of head to base of sixth cervical vertebra . . .	10

Total height, 5 ft. 10½ in., or 70½

The foregoing described portions appeared to belong to a person of between fifty and sixty years of age. The muscular system was well developed, and there was but very little adipose matter.

WINSLOW LEWIS, jun.

GEORGE H. GAY.

JAMES W. STONE.

Attest, J. L. ANDREWS.

Cross-examination of Dr. WINSLOW LEWIS, jun.—[The witness explained the anatomical terms.] Had been acquainted with Dr. Parkman about thirty years—quite intimate. It would not spontaneously have occurred to my mind that it was Dr. Parkman, if I had not known he was missing. Could determine the height of the person within half an inch, to a certainty. The perforation under the left nipple was much affected by some chemical agency. Discovered no marks of a knife on the ribs. A body of the size of Dr. Parkman's would contain about two gallons of blood. About two quarts of blood, or fluid, might be found in the cavities of a body of this size after death. Could not say how long it would take to burn up a head; I think it could be consumed in two hours, but cannot state that with any accuracy; it would depend upon the quantity of fuel. Could not determine the precise age of that body from the remains. There was more muscular development in the lower extremities than I should have expected in a body like that, in other respects.

Direct required.—If a person were wounded, as by the perforation in that thorax, he would, probably, have bled more internally than externally. A body ceases to bleed very soon after death, except from the veins.

Dr. JAMES W. STONE, *sworn*.—I concur in the report that was drawn up and signed by Drs. Lewis, Gay, and myself, and which has been read. The hair on the back of the body examined was much more, and longer, than usual, and of a sandy gray colour. The muscles of the lower extremity were more developed than one would naturally expect from the general size of the body, indicating that the individual had been accustomed to much exercise in walking. In front, on the left side, the skin was burnt, and the hair singed, so that its length could not be determined. On the other side, in front, the skin was not burnt, but decomposition had commenced near the right arm-pit. Judging from the skin, hair, and general appearance of the remains, the body belonged to a person from fifty to sixty years of age.

The amount of ossification of the arteries would seem to indicate that the individual was nearly or quite sixty years of age. There was nothing in the light colour of the skin, the sandy gray hair, the muscular development of the lower extremities, or the apparent age, which would conflict with the idea that it was the body of Dr. Parkman; yet, had I not known that Dr. Parkman was missing, I should not have suspected that these remains were portions of his body. My impression is, that the individual who separated the remains had some anatomical skill. It is difficult for a person who has never done it to remove the sternum, or breast-bone. I have seen good physicians, in a post-mortem examination, even when there was no ossification of the cartilages, give up the attempt to separate the sternum from the first rib and collar-bone, and break it off, leaving the upper part of the breast-bone unremoved. In this case, the incision through the skin and muscles was made, as usual, in the median line from the neck downwards, and the sternum properly removed, by separating it from the clavicle or collar-bone, and by dividing the cartilages close to the ribs. The divisions at the joints were rightly made, though somewhat irregularly. There was but little appearance of these remains having been parts of a subject for dissection.

tion. That which looked more like dissection than any other part was mentioned in our report, viz. an incision through the anterior portion of the external coats of the last six inches of the intestine, and a separation of them from the mucous coat. In preparing bodies for dissection, sometimes one injection into the arteries only is made; at other times, two or more. The first injection is made in all the subjects for anti-septic purposes. It is fluid, and usually consists of an arsenical solution, one of the chloride of zinc, or some similar preservative substance. This fluid is absorbed, so that it is difficult to recognise it, except by chemical tests. The second injection is solid, and is usually of glue or wax, so as to dissect for the arteries. That can be easily distinguished. There was in these remains no solid injection.

Cross-examination.—We examined the aperture between the ribs, to ascertain if it had been caused by a knife, as it was suggested that this might have been the case. In this place the skin was much softer than usual, from the action of fire, and the finger might easily have been pushed through the skin and muscles. The edges of the aperture were rough, as if it had been made by a stick. There was no mark produced by the cut of a knife upon the ribs. A day or two after, I heard that there was such a mark, but at the time of our regular examination, on Sunday, Dec. 2, we could find nothing of the kind.

Direct examination resumed.—There was no mark in this opening which had the appearance of having been made with a knife. The opening extended not only through the skin and external muscles, but also through the muscles between the ribs, and through the lining membrane into the cavity of the chest. The membrane and muscles between the ribs were perforated in other places, but nowhere with such regularity as would indicate that this had been done with a knife. I do not think that all the periosteum remained on the edges of the ribs.

Dr. GEORGE H. GAY, sworn.—I signed the statement that has been read, and agree to it. I saw the remains at the Medical College, and conceived that some anatomical knowledge had been exhibited in their dissection. The separation of the head from the spinal column is not an easy act. They do not use a saw to do it, except when they wish to throw the parts away. A person without anatomical knowledge could not readily cut the head off. It is not easy to separate the sternum from the clavicle. There was no indication, in the process of removing the thigh, showing that degree of anatomical exactness that would accompany the operation on the living sub-

ject. There are several methods of taking the thigh off from the pelvis. The hole in the chest I thought might be made by the pressure of the ribs, or the end of a cane, at the time it was removed from the tea-chest. I saw the remains on Saturday, but did not examine them so closely as I did on Sunday. I made an examination of the puncture through the ribs into the cavity of the thorax, and through the membrane internally, but saw no marks of a cut upon the ribs. I observed nothing more than was stated by Dr. Stone.

Cross-examined.—We examined merely to see the external and internal appearance of the perforation; I thought it previously done with a stick, and saw nothing to make me change my mind. I examined the skin outside, and the membrane inside.

Direct examination resumed.—It was on Saturday afternoon I first saw the body; the officer was poking off the tan from the part with his cane, with which I thought the perforation was made.

[To be continued.]

Correspondence.

THE MEDICAL PROFESSION AND UNDERTAKERS' FEES.

SIR,—I see in your number for August 23, a letter from Mr. Kesteven respecting some statements which have been made to the effect that some of the surgeons in London are connected, in a pecuniary sense, with undertakers. Mr. Kesteven has, with a most laudable motive, endeavoured to wipe away this disgraceful stigma from his profession; but a circumstance which occurred to myself tells me too plainly that certain unworthy members of it are in the habit of receiving fees from undertakers whom they may have employed. I will relate the affair.

Not very long after I had put my name on the door, I was summoned to see a gentleman who was quite a stranger in London, and who was taken suddenly ill: he died in three days. As the patient was lying at a coffee-house, and the weather was excessively hot, it was deemed advisable to have him removed at once. I therefore went myself to the nearest undertaker, who has a large shop, had the dead man removed to his house, and made arrangements for his funeral. This was supplied, and a large sum of money was paid for it. About a week or so afterwards, a tall, sombre-looking young man, wearing a white cravat, walked into my consulting room, made a most polite bow, announced himself as Mr. ———, the

undertaker, thanked me for having given him the job, and at the same time threw down on the table, with an air of great self-satisfaction, something of a metallic nature wrapped in a piece of paper. He also added that he hoped I would receive this small remuneration, and that I would employ him for the future.

Young in the profession, and inexperienced in the ways of this wicked world, I was taken quite aback at what looked very much like a disgraceful insult. I kept my temper, however, and told the maker of coffins that I was not in the habit of doing business in this manner; therefore I must decline his fee. He mumbled out some sort of apology, and quickly relieved me of his presence.

Now, sir, what tales does not this little incident tell? It impresses the conviction, on my mind at least, that there must be surgeons who are in the habit of receiving compensating fees from undertakers, otherwise this man would not have attempted to play the villainous trick upon one who was a total stranger to him.

I have no doubt that the same thing frequently happens to young practitioners in particular, and I sincerely hope, for the honour of our profession, that not any consideration whatever will induce them to take fee or reward of any kind from the undertaker, should it be offered: and I am sure you will agree with me that those who are actually in league with him must be totally devoid of all those sentiments of honour and propriety which should particularly actuate members of such a profession as ours.—I am,

Your obedient servant,

HENRY SMITH, F.R.C.S.

18, Caroline Street, Bedford Square.

THE MANCHESTER MEDICO-ETHICAL ASSOCIATION AND THE POOR LAW BOARD.

SIR,—We are instructed by the Council of the Manchester Medico-Ethical Association to request that you will publish the accompanying memorial to the Poor Law Board in the columns of your journal.

We are, sir,

Your obedient servants,

JOHN AIKENHEAD, } Hon. Secs.
W. C. WILLIAMSON, }

Manchester, Aug. 24, 1880.

To the Honourable the Poor Law Board.

THE Council of the Manchester Medico-Ethical Association beg respectfully to request the attention of your Honourable Board to a resolution recently come to by the Manchester Board of Guardians, involving certain medical regulations of an objectionable character.

It is proposed that a very widely-scattered district, containing at least 50,000 inhabitants, shall be assigned to one medical officer, whose remuneration shall be £150 per annum, out of which all medical and surgical appliances shall be supplied, he being at the same time debarred from private practice; and, further, that no extra fees shall be allowed for midwifery cases, or for surgical operations, except one shilling and sixpence for each successful case of vaccination, which latter, the Council have been informed, will probably not realize more than £50 yearly. There is reason for assuming, then, that an annual average of more than 2000 cases of sickness will have to come under the treatment of the medical officer.

Under such circumstances the Council submit that the salary proposed will not defray the necessary outlay in medicines and leeches; and as no other source of income will be available (private practice being prohibited), the conclusion is certain that the pauper patients will sustain the wrong.

The Council would further submit that the physical capabilities of one man, whose means will neither enable him to employ a dispenser of medicines, to use a conveyance, nor to engage the occasional services of an authorised substitute, will be utterly unequal to the conscientious discharge of the duties imposed upon him.

For the foregoing reasons, amongst others that might be advanced, the Council of the Manchester Medico-Ethical Association most respectfully call upon your Honourable Board to withhold your sanction to the resolution in question, as being one which must inflict certain hardship upon the poor, and involve the degradation of an honourable profession, should any one be found unscrupulous enough to accept the appointment upon the terms proposed.

Signed, on behalf of the Council,

J. L. BARRELLY, M.D., President.

J. AIKENHEAD,

W. C. WILLIAMSON, } Hon. Secs.

Manchester, August 23rd, 1880.

REMOVAL OF AN ENORMOUS FIBROUS POLYPE ATTACHED TO THE PHARYNX. BY M. ROBERT.

THE patient, a young man aged 20 years, was the subject of a large polype which filled the posterior nares, the mouth, and throat. M. Robert had great difficulty in ascertaining the size of the pedicle. The impediment offered to the functions of the parts imperatively called for an operation. M. Robert having removed a portion of the superior maxillary bone, succeeded in liberating the various processes of the

tumor, and tracing its pedicle to the superior and posterior wall of the pharynx attached to the vertebral column. The tumor with pedicle was detached entire by the use of the nails alone. The hemorrhage was arrested by the actual cautery. The patient recovered.—*L'Union Médicale*. X

THE CHOLERA IN EGYPT.

LETTERS from Alexandria of the 21st of August state that cholera continued to prevail throughout the country. At Alexandria there were about 50 deaths daily, at Cairo double the number, and throughout the Delta it exists more or less.

PROFESSOR WEBSTER.

PROFESSOR WEBSTER has confessed that he premeditated the crime of which he was found guilty. Friday last, the 30th ult., was the day appointed for his execution.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 29th August, 1850:—Robert Turner Bywater, Leeds—Thomas Evans Evershed, Billingham, Sussex—Thomas Roberts Hitchen, Herts—Charles Harriott Roper, Mount Radford House, Exeter—Robert Harrison Wilson, Howdon Pans, Newcastle-on-Tyne.

OBITUARY.

On the 23d ult., in London, after a long affliction, aged 40, Mr. Henry Thomas Clarke, surgeon, youngest son of the late Mr. William Clarke, of East Bergholt, Suffolk.

At Henley-in-Arden, on the 28th ult., Hugh Francis Burman, Esq., M.D., in the 35th year of his age.

On the 30th ult., at Derby, Wm. Baker, Esq. M.D. aged 60.

On the 30th ult., at his residence in Friar Street, Reading, in the 76th year of his age, John Bulley, Esq., surgeon, sincerely beloved and deeply lamented.

11. Premature Birth	31
12. Old Age	33
13. Sudden Deaths	9
14. Violence, Privation, Cold, &c.	32

The following is a selection of the numbers of Deaths from the most important special causes:

Small-pox	10	Convulsions	30
Measles	11	Bronchitis	39
Scarlatina	33	Pneumonia	33
Whooping-cough	24	Phthisis	130
Diarrhoea	118	Lungs	3
Cholera	4	Teething	6
Typhus	40	Stomach	2
Dropsy	13	Liver	8
Hydrocephalus	16	Childbirth	8
Apoplexy	20	Uterus	3
Paralysis	19		

REMARKS.—The total number of deaths was 196 below the average mortality of the 35th week of ten previous years. It will be perceived that there were only four deaths from cholera;—two of these (in adults) were cases of English cholera, and the remaining two occurred in children of five and eleven months of age respectively. There is not the least appearance of Asiatic or malignant cholera in or about the metropolis. In the corresponding week of 1849, 1,663 persons died of this disease in the metropolis. Diarrhoea is still very prevalent and fatal: there were 118 deaths from this cause during the last week. The deaths from scarlatina appear to be progressively on the increase.

NOTICES TO CORRESPONDENTS.

We are compelled to postpone our notice of the Poor-Law Medical Report until next week.

Dr. Hamilton's paper on the Statistics of Plymouth has been received; and, if possible, it will be inserted in our number of the 20th of September.

Mr. D. O. Edwards.—We wish to be informed when the *Atmoppyre* is in operation, in order that we may give the requisite information to our readers.

Dr. Tilt's second contribution will appear in the following number.

We shall be glad to receive papers in continuation from Mr. C. S. Bate, of Swansea.

Dr. Bucknill.—We regret that, by some accident, the Devon Lunatic Asylum Report has been mislaid. Could our correspondent favour us with another copy?

Communications have been received from Mr. Tucker—Mr. Galloway—Dr. Cox—Mr. Kirk. These will have our early attention.

ERRATA.—In our last number, page 357, col. 1, 20 lines from top, for "imbecility," read "imbecility;" and 24 lines from foot, for "possessed," read "possessor."—In leading article, page 372, col. 2, line 17 from top, for "probably," read "probably."—P. 380, c. 2, line 20 from foot, for "sulphate," read "sulphite."

Lectures.

LECTURES
ON THE
MEDICAL JURISPRUDENCE OF
INSANITY.

*Delivered in the Medical School of King's
College, Aberdeen.*

BY ROBERT JAMIESON, M.D.
Lecturer on Medical Jurisprudence in the
University.

LECTURE IV.

General description of the insane state (continued). (b) Intellectual condition of lunatics (continued)—Imbecility of mind—manifested in various habits and actions—exemplified—Imbecility in thinking—exemplified in writing—intellectual disorder increases with the prolonged effort at control—a lunatic's views of the insane conduct of other lunatics—may be aware of his legal position—the characteristics of lunatic epistles—exemplification of the expression of delusion. Incoherence—not a form of insanity, but a possible symptom in any form of the disease; best marked in mania and dementia—incoherence in monomania. Extravagance of conduct—the result of delusion—exemplified.—motives not traceable in insane actions—criminal deeds of the insane not indicative of viciousness—unsuitableness of insane actions to proposed object.

IMBECILITY is the next mental characteristic to be noticed; but, before alluding to the intellectual indications of it, I may specify some common actions and propensities in the lunatic state that manifest a general weakness of mind. In many, tears flow from very slight emotion, just as may be usually observed in cases of paralysis; and some are shaken by violent fits of laughter, apparently without any adequate reason. Laughter from slight or no cause is not an uncommon symptom in dementia—more common, perhaps, in female than in male lunatics. This risible propensity indicates no appreciation of humour: an indifferent impression on any of the senses may induce it: the sight of a stranger—a word spoken when there is silence—or even the motion of a finger. I doubt in many instances whether the laughter is even aware of his own mirth.

Weakness of mind is seen also in a childish facility of being pleased with trifles, showy articles of dress, silky orna-

ments, sweetmeats, and other things which, offered as consolation, a sensible understanding would despise, but which in a lunatic asylum are daily found advantageous in assuaging grief and conferring temporary pleasure. It requires no little attention to prevent many of the insane from making their personal appearance ridiculous by their dress. When they were more generally at large than they are now permitted to be, and when every village could show its fool, these poor objects could be distinguished by strangers by the monstrosities of their apparel.

Some lunatics exhibit a strange propensity to collect and amass together all sorts of unconsidered trifles. I was taken by an old man who had this crase to a small out-house in which he had collected a treasure of this sort, in which his whole soul was as much engrossed as ever a miser's was in his money, or a biblio-maniac's in his books. The collection, if not admirable for its value or rarity, was astonishing for its extent and variety of absolute rubbish. Pieces of old rope, filthy blacking-bottles, broken crockery, rusty iron, hens' feathers, showy rags, buttons, fish-bones, and a variety of other matters which had by oversight escaped the dunghill, were there laid up for admiration, and were esteemed by their collector a most attractive and imposing spectacle.

Certain demented persons find a childish amusement in jingling together words of a like termination. I have heard some of those who exemplified this whim go on making rhymes for an hour at a time, the similarity of sound in certain words seeming to be the only object in their continued utterance of an incoherent rhapsody. Others will go on reiterating some unmeaning convocation of words or phrases for the greater part of a day. I recollect one instance in which the attention to the sound of words took rather a singular form. The individual had become fascinated in some way by the sound of the vowel O, which he marked energetically whenever it occurred in his speech. This was, however, not so much an indication of mental feebleness as of obedience to an out-of-the-way delusion. He had the idea that there was a spell upon him impelling him to use this letter, and was no easy man to converse with, for he got furiously displeased with those that spoke to him if his ear detected the frequent recurrence of this vocalism in the words which they employed.

Feebleness of mind, instability of attention, and loss of self-control, are apparent in most things which lunatics attempt. The endeavour to instruct them in any new thing is a very difficult business, and,

unless in so far as it aids the moral treatment of the disease, very unsatisfactory in its result. Occupations of various kinds are now carried on in all good lunatic hospitals; but one sane workman would be able to work against two or three lunatics, and his work, under similar instructions, would be superior in quality as well as in quantity.

It is not an unfrequent thing for a lunatic to sit laughing and talking to himself without being aware that he is so occupied. I remember one particular example of an enfeebled mind in which the chief feature was that the patient, when left to himself, fell to talking aloud, his speech being sometimes at the full pitch of his voice, and the matter of it anything but agreeable to those who were within earshot. His talk, besides being noisy, was highly obscene, and rendered him such a nuisance both to his own house and the neighbourhood, that he was sent to a lunatic asylum. I found that in general he was not even aware that he had been talking at all, and when checked he would deny that he had been speaking ever so softly. When the matter of his discourse, however, was represented to him, he then allowed that he had been *thinking* in the way described, but persisted that if he gave utterance to his thoughts he was not aware of it at the time. He coined his thoughts into words without being sensible of his so doing. A person in such a state gives vent to much greater incoherence than his conversation ever manifests; and, accordingly, this gentleman, though evidently of enfeebled mind, was capable of conversing in a rational manner, and for any length of time, but the soliloquy of his solitary thoughts was a most lunatic rhapsody. The act of conversing with such an individual serves the purpose of steadying his thoughts, the part which a second person bears in the conversation affording points of direction and support to the vagrant attention.

Imbecility in thinking is always in a greater or less degree the accompaniment of insanity. The ideas of the insane become objects that they are no longer able to deal with by voluntary effort. Volition has not weight sufficient to make such an impression as will regulate their course. Unless the ideas can be effectively dealt with by the natural amount of power in regulating and controlling their succession, the processes of attention, memory, and comparison, must be impaired, involving with them the faculties of abstraction, imagination, and judgment. The very endeavour of a lunatic to influence the current of thought serves often but to increase the confusion; and, if he manifests imbecility in thinking in conversation, in which

he has the directing aid of another, he is likely to make that imbecility still more apparent when he is left to himself, and allowed to attempt giving utterance to a chain of connected and related thoughts. The attempt to write upon any subject is the one which will render the intellectual derangement most plainly manifest; and, in a medico-legal view of insanity, it will not be throwing away your time to give a few examples of failure in converting thought into thinking, and thinking into words. These I select not so much as being the most characteristic that might be given, but as the most convenient, from their brevity, and the absence of circumstantial and personal allusions. You are to understand that they are examples rather of special than general lunacy, and also that they are the production of those whose education and acquirements enabled them at one time to make a very different exhibition.

A gentleman whose mind had fallen into a state of feebleness, the consequence of a previous maniacal condition, but who could in the slightest effort of ordinary conversation manage to pass muster tolerably well, thus displays his inability to deal with his thoughts when he attempts to write a short letter. His object in the example which I am about to give seems to me to be to express something like the following ideas:—I have no particular object in writing to you at present, unless to take advantage of our former intimacy, and to prove that I consider it a duty to remember you; and I hope that, whatever circumstances occur, we shall still continue to have the same friendly feeling toward each other. Such may, I think, be considered the aim of the epistle. It would be a weak mind that would resolve upon sending a letter with no other object than the above, unless it were to be made a longer and more interesting communication than such a brief statement would be. The way in which he succeeds is this:—"My dear sir,—I cannot but exercise a reclaiming petition in my favour, and therefore bring to view the social intimacy in which we formerly stood connected, and in compliance soften the obligatory duty. We may still aspire to a tangible hope at least to meet the crisis of passing events, and in fellowship conciliate our conditions in like manner. The confiding heart will then furnish its results to a merited condition. With the basis of these propositions suffer me to conclude, with the greatest esteem, your dutiful friend, &c."

Here is another instance of a similar kind:—

The patient, in consequence of having received a visit from an acquaintance who

invites him to pay a visit in return to his house, thinks it necessary to make a written acknowledgment of so much attention, and acquits himself as follows:—"I was particularly happy at the pleasure to see you last day, and more particularly the most discriminate satisfaction to learn of the manifest surety of all terminating to a good effect." (His friend had probably consoled him with the assurance that he would regain his health and freedom.) "I cannot too much estimate the agreeable confidence reposed in me, and the marked attention so constituted of the family, and even friends. This ought to give me a conviction of the good society and ability of influence in point of politeness with whom I judge versed to form acquaintance: If I could see your place I think I should find it curious." (This is not a piece of naïveté in allusion to his restricted freedom, but merely his mode of saying that his friend's residence was well worthy of a visit.) "My motive would be chiefly to see it both as regards natural and that of superficial connection as to improvement. I beg to be most kindly remembered, and I am, &c."

It usually happens that the confusion of ideas gradually increases with the prolonged effort to express them. The first replies of a lunatic to a course of questioning constitute the best exhibition of his faculties; as the conversation continues the replies become more and more insane in their character. The same thing is often exhibited in writing. The following is rather an amusing example:—"One of the gardens to which the patients in a lunatic asylum had access having fallen into a state of disorder from neglect, an inmate who had something of a taste, though an insane one, in horticultural matters, chose to make the following report on the subject:—"In regard to the southern airing ground," writes he, "the shrubberies and flower-plots would be much improved by some attention to the same; therefore the rose-mounts might have a little manure added to the soil, as this appears to be the primary point with respect to these, and cleaned out, and the roots kept free of each other as well as the bushes. The general effect otherwise may speedily be got in trim, when it may form altogether a free and genteel aspect. The box edging may also form an important source of interest to the occupiers by doing it neatly, and at the same time not to lower their proper estimate of themselves as subsidiary exercise for a short time. No doubt it would have been in better order had it not been for the injuries it sometimes receives by the poor invalids that practise their much to be deplored folly; but when the heart of influence has got an acting corrective guide, it sweetens every effect to impress the mind with the

beauties of nature and the direction of man, generally speaking." The reporter gets on very well for a short space, but ultimately loses himself in a maze of words. The "much to be deplored folly" so complacently referred to, and which in the epistle is the initiatory phrase to the deplorable folly of the writer's own words, shows that a lunatic may be perfectly aware of the insanity of his companions, though insensible to his own deficiency.

It is, however, not an infrequent evidence of the diseased imbecility of the intellect to find that the lunatic is not cognizant either of his own or of others' delusions. He is unable to discover anything extraordinary in the conduct of those around him. A maniac he considers to be a very lively person, something too much so perhaps; but he is not struck by anything irrational in his behaviour. It is often the first mark of convalescence for a patient to become sensible to the absurdities of his companions.

I may here direct your attention to the fact that lunatics, though blind to the defect of their own judgment, are often sufficiently aware of the estimation in which they are held by others, and have a perfect knowledge of their irresponsibility in the eye of the law. For example, a lunatic seeks to gain his freedom by bribing his attendant with a promissory note for a considerable amount, and in a private communication to one of his friends tells what he intends to do, remarking that of course there is no danger of loss to be apprehended, for that his position incapacitates him from being lawfully a party in any agreement. This might be pleaded by the patient's curators or his heirs, but not at any time by himself; for it is a principle in law that no man shall stultify his own acts. Not long ago, under my own observation, an insane patient made the attempt to destroy the life of his attendant, who was at the time in a stooping position, by suddenly snatching up a spade and aiming a blow at his head. Manslaughter, he said, was of little consequence to him, for no madman is punishable by law. You will find many instances of a similar kind on record, and in regard to them all you will notice that they occurred in persons who knew that they were considered to be insane: indeed, they are all related of patients under restraint; and such speeches do not indicate that the individual is aware of and believes in his own madness, but only that he knows that he is accounted insane. No person, therefore, who falls suddenly into the state of mental derangement and commits a deed of violence, can be supposed to do so because he knows that he will be exempted from punishment on account of the

state of his mind. A criminal lunatic does not believe in his own insanity at the time that it is pleaded for him by his counsel. He may become aware of his legal position only when experience has taught him how his conduct is judged of by the world.

The following short attempt at letter-writing is a lamentable example of imbecility: it was nearly the forenoon's occupation of one who was in his time reckoned a very clear-headed and intelligent professional man:—"Dear sir,—You are directed pull down all authorities municipalities and powers in which I am invested, and to regard me as extinct and not monumental. You are feudally you hereby required to remodel all authorities powers and dignities but not you are in my name not for the space of five days less or more not exceeding ten years but not in my name not not.—Yours, &c." The production, to be duly appreciated, would require to be seen. It evinces besides delusion great decay of the faculties of attention and memory, and an extraordinary inefficiency of the voluntary power over the current of thoughts.

Though the examples given are all of a brief kind, you are not to suppose that brevity is the characteristic of insane epistles. And here I may take the opportunity of making a few observations on such productions. The letter of one labouring under mania will bear every possible evidence of his condition. The handwriting will not be like his ordinary handwriting; the page will be blurred, blotted, and disfigured; the words frequently misspelled, omitted, and misspelled; the letter probably grotesquely folded, and put up in some absurd way; and the matter rhapsodical, incoherent, and influenced by his delusions. Such a communication is not likely to be very long. On the other hand, the letter of a monomaniac will probably be very much the opposite of terse. A monomaniac, as he never wearies thinking or speaking of his delusion, does not condense when he comes to deal with it in writing. Such a letter, while it may be tolerably connected, and manifest possibly considerable activity of mind, will usually be found to be of a most extravagant length. He knows no limitation but the amount of paper he can at the time command. It will be like a web of inky tartan, crossed and re-crossed; warp and woof of it covered with his insane crêchet,—his insane crêchet alone. Many of the partially demented have also a great plenty of words,—so great, that they could apparently continue writing for ever. Such productions are distinguishable from the profuse communications of the monomaniac by the constant incoherence of thought and language displayed in them. When the imbecility of mind is great the epistle is

very short, from evident want both of ideas and words.

The epistles I have adduced have exemplified the intellectual feebleness of the insane, rather than their diseased imagination and loss of judgment. I shall now finally give you one example of the expression of delusion: it is to this effect:—"A mutual friend informs me that he was with you this morning, and that you was expressing a desire of hearing from me. It is a very long time I have been here, almost fifteen years. I have seen you twice. If you would give me a call occasionally I would take it as a favour. For what reason have I been here such a length of time? As a madman or an idiot? No! There is not a madman or an idiot here, and has not been during the time I have been here. For what purpose, then, are they or I here? Am I here voluntarily? What say you? You know I am not. We who are here are all operated upon by zinking mechanicals. I should think by this time the nature of these is in some degree known beyond the walls of this place, and that yourself knew something of them. Their operation is now general over the whole earth, from pole to pole, and from east to west. Of the structure of the mechanicals I am ignorant. A chief part of them, I understand, is under the surface of the earth. From information given me through my own mouth by some of those persons who operate by means of these mechanicals, I understand that this globe is not a spheroid, but of the shape of a kettle-drum, an instrument used for music. The crust does not in any point exceed a thousand miles, in some cases not half a mile. The latter takes place at the bottom of mountains. The thousand miles is at the pole. The other part of the interior of the globe is a cavity, with light equal to that at the pole in December. The extent of the cavity is from one thousand to twenty thousand miles. In this cavity the zinker is placed in a balloon, in which he travels with the speed of electricity: besides this, he has the benefit of the earth's motion when twenty or forty miles below the surface. He perforates whenever he wishes to make observations. A new era has taken place in medicine. The zinkers have already surveyed all the inhabitants of the globe, and, according to their information to me, of the correctness of which I have no doubt, they have improved the breed of the human species. Their work in curing and preventing fever and other diseases affecting the general system is silent, and perhaps almost unknown. Cases, the cure of which would be considered miraculous, are not yet completed, although I understand entered upon. These are cases of

blindness, deafness, and lameness. These in all possible varieties have been surveyed, and are all curable, and to be cured, over the whole earth by means of the sinking mechanicals. When?—I am yours, &c.”

Incoherence is an indication of the intellectual disorder in insanity on which I shall not long delay. Suppose that a person of sound mind were to give utterance to his internal thoughts just as they arise, the soliloquy would probably be a very rambling one, but it would not be incoherent. He would be sensible of the relation that regulated their succession, and even an auditor would be able to trace something of the connection of each thought with those that preceded it and those that followed. There would doubtless be certain links that had a disjoined appearance, because every one has certain special ties of association that are peculiar to his individual habits and experience; but on the whole there would be evidently a method in the thinking, and intelligible relations betwixt the several ideas. The incoherence of lunacy is not merely the expression of the vagaries of an unreined imagination. In its highest degree it is a string of ideas that have no relation but that of sequence, a sequence of *non-sequiturs*, so to speak. Incoherence results from all causes that occasion loss of voluntary power over thinking and expression. It may be the temporary consequence of undue emotion, the necessity of influencing delusion, the evidence of impaired memory, or of distracted or enfeebled attention.

Incoherence has sometimes been termed a form of insanity, and the word used as synonymous with a variety of dementia; but though a symptom which is best observed in dementia following mania, it may be a feature in every form of insanity. It is a more usual and more early symptom in the mental disorder of the weak-minded and the uneducated, than in that of the better endowed and better instructed. In mania, whenever the excitement runs high the ravings of the patient are remarkably unconnected. In such a condition the symptom originates in a distracted state of the attention, occasioned by the delirious course of images through the mind when the associating faculty is deranged. The speech is often seen to be a tissue of half-expressed thoughts, the images following each other so rapidly that language cannot overtake them. In dementia, incoherence is the language of an enfeebled and unstable attention. This faculty is the union of perception with desire, but in those who have fallen into the state of chronic dementia the voluntary element of action has become so impaired that the faculty of attending is almost

lost. Haslam gives an illustration of this state of the mind in the case of a man who was unable to tell any story straightforward from beginning to end. He would begin with the best intentions, and proceed a little way tolerably well; but the chairs and tables, and all the objects around him, a hat hung upon a peg, or an ornament on the chimney-piece, would become interwoven with his narrative, and lead him from subject to subject. The demented are loquacious about things which have neither sense nor connection, reason nor rhyme. “They speak,” says Feuchtersleben, “in the same breath of sabres and toothpicks, children and hats, broken pitchers and dismantled ships.” In these cases of partial insanity, so called, in which the patient is said to be insane on one subject or set of subjects, it is common enough to find, especially when the case is of some continuance, that, however collectedly the patient may express himself on other subjects, upon this his weak point he cannot give utterance to his thoughts in a coherent strain. The patient is not unsound in mind simply as entertaining a delusion, but still further intellectually disordered that he is also incoherent in reference to his error in judgment. A monomaniac is frequently not merely deluded, but unintelligible: deluded, and incoherent on all points connected with his delusion.

Extravagance of conduct.—The intellectual disorder of lunatic patients, besides being manifested in delusion, imbecility of thought, and incoherence, is also seen in their actions, in unaccountable deeds of violence, unnatural impulses, irrational attempts at impossible ends, unfruitful experience, and an insensibility to many forms of discomfort.

Where not merely automatic or instinctive, lunatic actions are the result of the instigation of delusion, though the connection is not always to be made out. Deeds which seem to be incomprehensible may owe their absurdity not to want of premeditation or design, but to insane reasoning in connection with a hidden governing delusion.

An excited maniac spent his time mostly in turning somersets on the ground, which was certainly an absurd and dangerous occupation for a person past his boyhood, and whose business was the grave study of theology. There was no alleged or apparent motive, and little other indication of delusion. I came to understand, from his own information afterwards, that this was done at the instigation of a voice in his head, which he made of worship most

often. He had a strange propensity to enter the interior of chimneys, to

the great danger of his life: in truth, he narrowly escaped suffocation and burning. He was for a time constantly bent on this as the great aim of his existence. It was an action which no one would pretend to understand, unless as a peculiar kind of suicidal inclination, which however it was not. He told me after his recovery that he believed that the only way in which it would be possible to persuade mankind that he was truly the emperor of Russia, as he then supposed himself to be, was by ascending to the roof of the house in that manner. He was a silent lunatic whose actions were the source of much care and anxiety, and whose delusions could never be surmised.

Professor Alfred Taylor adduces a case which seems usefully illustrative here,—the case of a young man whose insanity led to a criminal deed such as never could have been anticipated from the character of his delusions. "He was a person of mild manners, and laboured under a delusion connected with windmills. He would go any distance to see a windmill, and would sit watching one for days together. His friends removed him to a place where there were no mills, in the hope that this strange propensity would wear away. He enticed a child into a wood, and in attempting to murder it, cut and mangled its limbs with a knife in a horrible manner. How would any sane person," says he, "have connected this delusion with attempted murder? Yet it turned out that he had taken the resolution to commit this horrible crime in the hope that he would be removed as a punishment to some place where there would be a mill."

The violence and destructiveness of which the insane are at times guilty, is often not the evidence of viciousness, but the consequence of disordered reasoning. For example: a maniac, during his paroxysms, amongst other acts of destructiveness used to occasion much trouble by tearing his shirt and bedding into shreds during the night. After recovery, he accounted for so doing in this way. He said that he was perfectly aware of what he was about, but that he had no idea then that it was anything wrong; on the contrary, he did it more to please others than himself, and actually believed that it was a very meritorious action which would do some vague kind of good to himself and others, provided he succeeded in tearing the articles into certain determined shapes. He was very much disappointed to find when visited in the morning that he was blamed instead of being praised by the attendant; and this he attributed not to having torn his bedding, but to his not having succeeded in making the fragments of the proper shape.

In the published narrative of one who experienced and recovered from a lengthened attack of mental derangement, the same absence of malice is prominently represented. "I knew no malice," he says, "no vice. I imagined that the keepers loved me and were all deeply interested in the salvation of my soul; and I imagined, too, that I loved them dearly. Yet I wretched with them, and offered to do so with others, and struck many hard blows, sometimes, as one informed me, making it difficult for three men to control me; yet, whenever I did this, I was commanded that they wished me to do so, to prove my faith and courage, but that they were commanded to prove both till they were satisfied of my sincerity." "It was a great delight to me to get my hand at liberty, even for a moment, and the first use I usually made of it was to strike the keeper who untied me directed by my spirits to do so, as the return he desired above all things else, because he knew I was proving my gratitude to the Lord Jehovah at the risk of being struck myself."

Thus you will observe, many criminal acts might be done by a lunatic without a criminal motive. He might know abstractly that it is wrong to burn or destroy without being aware that the particular deed of violence which he is committing is any other than good and praiseworthy. We are not likely to trace the motive in the action that an insane person has committed, nor, although he may have set about the action, and carried it out by the very means and in the very way that a sane person might have done, can we infer that he therefore was in a position to distinguish right from wrong.

The acts which a madman performs in obedience to his delusion are frequently not merely unindicative of their motive, but ridiculously unsuitable to the object intended. A patient walking about one of the gardens of an hospital, generally picked up little stones and threw them over the wall, because she understood that the house was by and by to be consumed, and she wished to make her escape. She never attempted to force the door or climb the enclosure, nor did the experience of any preceding day suggest the futility of her persevering in this mode of seeking her object.

M. STROMMEYER.

THIS eminent Prussian surgeon was wounded in the battle of Idstedt, taken prisoner by the Danes, and conveyed to Copenhagen. He was immediately set at liberty by the Danish Government.

Original Communications.

ON THE
ORIGIN, CAUSE, AND NATURE OF
CHRONIC OVARIAN TUMORS.

BY EDWARD JOHN TILT, M.D.

Senior Physician to the Paddington Free Dispensary for the Diseases of Women and Children, &c. &c.

Fibro-serous Ovarian Cysts.

WE have already pointed out that cysts may be developed in the cells of the ovarian cellular tissue by a process of hypersecretion dependent on the increased action of its innate powers, and that they may also originate in extravasated blood—the only ways of accounting for the fibro-serous cysts of the broad ligaments. We have, however, in the disturbed secretions of the ovarian follicles, a much more frequent origin of ovarian cysts. Considering the ovarian follicles in the whole tenor of their monthly career, pathological anatomy obliges us to admit that these follicles frequently neither arrive at perfection, nor do they succeed in bursting the thickened ovarian sheath and the peritoneal membrane, which may be covered with false membranes. The little cyst thus originated may go on increasing; but, unless inflammation intervene to give increased impetus to the exhaling process, such formations are arrested in their progress, and we find traces of their existence in those gary, puckered, withered sacs, which Delpech erroneously considered a new kind of cyst, whereas we merely view them as an instance of Nature's power in healing these small cavities, as she sometimes does much larger cysts, by the absorption of their contents. Generally speaking, the ovarian follicle bursts, and the remaining cavity is filled by a blood clot; and, when we consider that the peculiarly-organised body, or corpus luteum, often occupies two-thirds or more of the whole ovary, as may be seen by a glance at the preparations in the museum of the College of Surgeons, we cannot but admit that, notwithstanding the adaptation of the whole energies of the ovary to absorb the corpus luteum, this process may sometimes be arrested, or so disturbed as to brigrate an ovarian cyst of an hematic origin.

This is no fanciful assumption, for in four instances Pouchet found a fibrinous clot in the corpora lutea of sows; and it stands to reason that a clot of blood so situated may undergo the same changes as it does when deposited in the brain or in the cellular tissue;—or, in other words, that it may be transformed into a cyst, and, once formed, it has within itself the power of increase. Duplay and Teissier have, we believe, indicated this possible cause of ovarian cysts. Ruysch, Kruger and others, struck by the great size to which the yolk-bags sometimes attain, have supposed that small ovarian cysts were cases of unfulfilled pregnancy, and that the ovula themselves, imperfectly formed, may protrude from the bursting vesicle, and, remaining attached thereto by inflammatory adhesions, develop themselves unimpregnated, and produce those small pendulous cysts which hang so frequently from the ovary, or from the fimbriated extremities of the oviducts. But this explanation cannot be received in all cases, for it would not account for similar bodies found pendent from the broad ligaments and numerous reflections of the peritoneum; and, when we consider how often the fimbria are in contact with menstrual blood, we cannot but attribute an hematic origin to the little cysts which so frequently are appended to them, or to the interior of the Fallopian tubes. Dr. Bright has published an interesting case, communicated to him by Dr. Beaumont, where innumerable pendulous tumors like polypi, transparent and filled with a watery fluid, some the size of a small pear, were attached by threads to the reflections of the peritoneum. These appearances seem to indicate a secretion settling into a precise form, and are analogous to certain uterine vegetations which are of a gelatinous or cartilaginous consistence, and divided into one or more cells containing a clear serous or a gelatinous fluid. We are inclined to ascribe to both descriptions of bodies an hematic origin, and we shall support our views by giving a case published by Andral (*Precis d'Anatomie Pathologique*, vol. ii.):—

“On opening a patient who had died of ascites, I found red serum effused both in the peritoneum and in the pleuræ. The pleuræ were covered with little round bodies of different sizes: some were mere clots of blood, but

others presented the different stages through which the clot passes before it assumes the pale colour of fibrin. These bodies adhered to the serous membrane by cellular or vasculo-cellular prolongations, and four or five of them were full of a milk-like fluid. The peritoneum presented similar bodies, some like blood-clots, but most of them looked like gray and white bodies full of a matter having the appearance of cream. Some of the intestinal lymphatics contained a similar white matter. After an attentive examination of these little bodies, it appeared to me evident that all of them had the same origin; that they had all been blood-clots, which, on being organised, had become the seat of a morbid secretion. I have met with numerous instances of a similar morbid process."

We have thus established that the fibro-serous cysts may originate—1. in the cellular tissue of an ovary; 2. in the follicles of that organ. With regard to the follicular or multicystic variety, we believe that it is always found in the ovarian follicles. We cannot in any way admit, with Dr. Hodgkin, that such cysts are formed by the primary cyst generating the secondary, and these again the tertiary,—an explanation which we have admitted as satisfactory for certain complicated forms of fibro-serous cysts; and in order to account for these formations, we can only suppose a general hypertrophy of the whole tissues of the ovary, which, if magnified by a solar microscope, would itself present an appearance something similar to that of these strange multilocular tumors.

Having enumerated the various origins of ovarian cysts, we are now better prepared to inquire into the value of the causes which prompt their development. These causes are—I. Predisposing; II. Exciting. 1. The predisposing causes are—*a*. The functions of the ovaries; *b*. The constitution of the patient.

a. With respect to the structure and functions of the ovaries as predisposing causes of ovarian cystic tumors, we may, perhaps, be permitted to observe, that in fishes and birds the ovaries are distinctly formed of vesicles clustered together, sometimes exactly resembling pseudo-hydatid structures; and that in many of the mammalia, as in the sow and the hedgehog, the vesicular dispo-

sition is also apparent; that in the ovaries of the *fœtus* minute vesicles are distinguished embedded in the stroma; and that the monthly duty of the ovary is to elaborate the menstrual cyst: but sufficient having been already said upon this subject, we shall merely add, that the cystic structure of the ovary, its periodically increased flow of blood, and its stimulation by coition, conception, and pregnancy, are predisposing influences, the moments or cumulating effect of which must powerfully tend to increase any morbid growth which may have once taken root. Why should we feel surprised if the morbid operations of the plastic force are most seen in those organs wherein vegetative power has been centred for the propagation of mankind, and if ovarian tumors are most frequent at that period of life when all germs of disease in the genital organs rapidly spread?

The predictions of physiology are confirmed by statistics; for ovarian disease generally begins in that interval comprised between the first appearance and the cessation of menstruation. That its appearance coincided with the disappearance of the menstrual flow was formerly believed; but if we add 260 cases, collected by Dr. Chereau, to 60 of our own, and then deduct 40, wherein neither the age was clearly marked, nor the particular time when a tumor was first perceived by the medical man, we find that the origin of the disease was observed to occur between the ages of 37 and 47 in 106 women, and between the ages of 17 and 37 in 130 cases. According to a table made by Mr. S. Lee, we find that in 140 cases

45 began from 30 to 40 years		
37	"	20 " 30 "
26	"	40 " 50 "
17	"	50 " 60 "
3	"	60 " 70 "
2	"	70 " 80 "

We also obtain an insight into the period of life in which women are most liable to such disorders, from the reports of the Registrar General, which, valuable as they have already been, acquire every year an increased perfection, which they owe to the enlightened and persevering exertions of a member of our profession, Mr. William Farr.

I have been permitted by the Registrar-General to extract from unpublished documents the following figures.

Deaths caused by Ovarian Dropsy in London during the Year 1848:

Years.	Deaths.
20	2
25	1
30	6
35	4
40	7
45	8
50	2
55	5
60	5
65	3
70	1

Deaths . 44

Here, again, we see the majority of deaths occur between the ages of 30 and 45; and no doubt many of the deaths which occurred at a later period were owing to the disease which had originated many years before.

Ovarian cysts may be developed independently of the menstrual *aisus*; for Bergstrand (Hamburgh, 1837) found the left ovary of an infant dropsical, and much increased in size. Meyer, of Bonn, met with a case of multicystic ovary in an infant of 2 years. Schatel (Wurtemberg correspondent) found twenty-five pints of serum in an unilocular cyst in a child. Itard saw an ovarian cyst in a girl of 13; and Frank, one at the age of 14. Dr. Ashwell has known the disease to appear at the same time as menstruation in a girl of 14; and Dr. Cheveau has had a similar case, where the girl perceived a swelling soon after the first appearance of the catamenia. It is necessary to remark that Morgagni and the older writers, as well as Meckel, Boyer, B. Cooper, Chelius, and others, thought it sufficiently proved that the left ovary, which is the most frequently attacked by acute ovaritis, was also most liable to chronic disease; but statistics seem to prove the contrary; for, by adding to those we have seen the number of cases given by Chereau, Lee, Kilgour, Bluff, Tavignot, we find 475 wherein the side affected was specified: thus—

The right side	260
The left	173
Both sides	42

Dr. Clay also mentions that nearly four-fifths of the cases he has seen have been on the right side.

Professor Owen says that, as a general rule, the right and left oviducts and testicles of birds are at first equal in

size, but that the left organs alone attain to that state of development which qualifies them for several functions. It was probably to the unknown cause of this singular fact that Carius alluded when he explained the *supposed* greater frequency of ovarian disease in the left ovary by what he called "the ruling productivity of the left ovary." German transcendentalists will now be obliged to explain the greater liability of the right ovary to disease by admitting that the ruling productivity has changed sides.

Some facts may be adduced to show that this disease may be hereditary: thus Meissner mentions "that Alt lost his daughter at ten years of age, and that, on opening the body, an ovarian degeneration was found, similar to that which had caused the death of her mother;" and Campbell (*Midwifery*, p. 176) says that he was informed by one of his pupils that nine sisters were all attacked with ovarian disease!

Constitutional diathesis.

Cystic growths have been often considered the expression of some constitutional perversion of the fluids, either cancerous or scrofulous. Ledran first started this opinion, considering ovarian dropsy as the epiphenomenon of scirrhus, —a term not very definite now, but most indefinite in the time of Ledran. This opinion has been admitted by Delpech, and partially so by Cruveilhier and Mad. Boivin; while in our own country Dr. Bright and Mr. Bransby Cooper have allowed the same explanation. That certain fibro-cartilaginous tumors shall have been mistaken for scirrhus is not surprising; but the denomination of *malignant*, applied by Dr. Bright to many forms of ovarian disease, is neither warranted by the general structure of the tissues, nor by their microscopical investigation. Having met with several remarkable instances of real cancerous ovarian cysts, and finding it difficult to distinguish between these and the simple forms of ovarian cysts, it seems as if Dr. Bright tried to elude the difficulty by calling the latter *malignant* tumors of a mild nature. Even the little innocent pendulous cysts are thus termed malignant. If this were true, we should more frequently see ovarian dropsy of long standing complicated by the cancerous lesion of some other organs, whereas the complication is rare. Professor Reclamier, during his long practice, can only

remember two cases of cancer coinciding with ovarian disease. Again, if this were tenable, we should, in the numerous cases of rupture of the cysts with effusion of their contents into the peritoneum or other organs, have at least sometimes seen the propagation of cancer to those organs. As this is not the case, we may dismiss the subject; admitting, however, the liability of the ovary to cancer,—a form of ovarian cysts which we have already described. If only a small proportion of ovarian growths derive their existence and peculiar nature from a cancerous diathesis, we are convinced that a large number owe their origin to a scrofulous modification of the tumors. That delicate lymphatic subjects are the most liable to these forms of disease, has been long remarked; and we believe Mad. Bevin was the first to consider them as accompaniments of this temperament: St. Jefferson, Copland, and Cruveilhier, adopt the same view, and we hold it to be correct. If we consider the topographical situation of the disease, an etiological element which ought to stand first in every similar investigation, we find that in hot climates, where the scrofulous taint is little observed, ovarian disease is likewise of rare occurrence. It is not known in India. Dr. Davey, of the Ceylon medical service, has assured me that during his five years' residence in Ceylon, and attendance at a dispensary in Colombo, where the native women, out of a population of 200,000, willingly sought advice, he never met with a case of ovarian dropsy, although ascites and anasarca were not uncommon. During our residence in Egypt and in Syria, our own observation, and the experience of those who practised in those countries, taught us that it was not to be met with there. We have been assured by our friend Dr. Thompson, who practised for four years in Damascus, which boasts of a population of 250,000 inhabitants, that he never saw a single instance of this disease. Dr. Ross has also told us that, during his ten years' practice in Madeira, it has been very seldom observed by him; and during a long residence in various parts of Italy, we never met with a case, and the native practitioners assert that it is not of very frequent occurrence.

In answer to some questions which I addressed to him through the Colonial

Office, Mr. Ferguson, Government Surgeon of Western Australia, assures me that ovarian dropsy is commonly met with amongst European settlers, whereas it is unknown to occur in the native women of Western Australia,—an immunity which may be the effect of race as well as that of less sophisticated habits.

We must turn from these sunny climes to those temperate regions where, for the greatest part of the year, the sun has not sufficient power to warm into healthful life the dull fluids which circulate in our veins. We must come to France, England, and Germany, where, to retain their warmth, the inhabitants must submit, the greatest part of the year, to be cooped up in a small quantity of more or less contaminated air. We must turn from countries for the most part thinly peopled by those who, amidst all their failings, still follow some salutary principles for the perpetuation of their race, to those highly civilized countries where, in certain spots, millions are assembled, and are so huddled together as to obstruct the vivifying rays of the sun, to contaminate the air and poison the water,—enlightened races, most anxious about the purity of the blood that flows in the veins of bulls, or sheep, or horses, but who do not care by what impure blood they may contaminate their own perhaps not less impure, reckless as to whether their descendants are destined to inherit scrofula, gout, cancer, or even madness—that still more terrible canker of the mind. Shall we then wonder when such blood becomes more and more vitiated in a population, when it is prohibited, by act of parliament, to revivify it by the regenerative influence of air, light, and water? can we wonder that scrofula should be common amongst us, and that from this heteromorphous mass of fluid there should spring, in various parts of the body, heteromorphous growths? Now,

* We do not seem to be sufficiently aware of the fact that the modern researches into the nature of the fluids of the human body by physiologists and chemists lead us far away from the exclusive dogmas of solidism, and will soon force us again to adopt the long-despised doctrines of the humorists. It is true the microscope is supposed by some to give us, in the knowledge of the cell, the ultima thule of physiology and pathology; but the investigation of the cell is only a more minute species of anatomy, and those who think to find therein the ultimatum ratio of health or disease will be sadly deceived.

Already do some of the most distinguished

although ovarian encysted tumors may be met with in all constitutions, the scrofulous generally coincide with the heteromorphous growths I here describe. If, however, from speculations we turn to facts, we find that in many of the cases recorded in medical journals, the strongly lymphatic tendency of the patient has been noted. For instance, the ten cases given by M^d. Berwin (*Mémoires sur une cause de Favorisements*) occurred in women of a similar constitutional tendency; and thirty out of the fifty-three cases we have treated, or whose treatment we have carefully followed, had the attributes of a lymphatic constitution; and had been affected by glandular swelling, swellings of the joints, scrofulous ulcers, or by phthisis.

ON THE OPERATION FOR THE REMOVAL OF SCROTAL TUMORS, &c.,

THE EFFECTS OF MESMERISM AND CHLORO-
FORM COMPARED.

By JAMES ESDALE, M.D.
Marine Surgeon, Calcutta.

I AM induced to address you in consequence of having read, in the February No. of the MEDICAL GAZETTE, an account of a fatal operation performed at Alexandria for the removal of a large scrotal tumor. As I have probably performed more operations of this description than have taken place all over the world, you and your readers will not be displeased perhaps to learn the practical results of so extensive an experience.

From the rarity of this disease in temperate climates, this operation is

microscopists of the North acknowledge that they must look beyond the cell, and more closely study in the different tissues those molecules and granules of which cell-growths are the perfect development. But beyond the granules there are the fluids, in the midst of which, and out of which they were elaborated, and in which they will again be dissolved; and although these do rank below the solids in vital capacity, it is now well proved that even from the fluids the vital principle can build up fibres and membranes, whether in the normal or the morbid state, without the intervention of either molecule, granule, or cell. Thus we are again brought back to the fluids, and to the universal fluid, the blood, which still maintains its unity of composition, despite the elements incessantly withdrawn from it by so many organs, and the refuse with which they continually pollute the purity of its stream.

When chemical poisons are introduced into

comparatively a novelty to European surgeons.

These singular and often prodigious tumors are so common in Bengal, that they may be considered as an endemic curse of the climate. The disease in a great measure is confined to Bengal and the sea-board of India. A hot, moist, malarious, and relaxing climate seems to favour its invasion, as it is rarely met with in Upper India. In Egypt it is also principally confined to the Delta of the Nile, and is seldom seen above Gairo. It is also prevalent in the West Indian Islands. All these tumors are generally called "elephantiasis of the scrotum;" but this is incorrect, as simple hydrocele is probably the origin of nine-tenths of those here, the remainder being divided between syphilis, leprosy, and elephantiasis. There is a most remarkable predisposition to hydrocele prevalent among this population, the extent of which may be imagined from the fact that about 2000 cases are operated upon yearly in the hospitals of Calcutta; and this is the perennial source of the inexhaustible supply of this kind of surgery.

The native treatment, which is worse than useless, is to make deep eschars in the tumor with red-hot charcoal balls, which often brings on an intense inflammation, deep sloughing, and fatal hemorrhage, and never, as far as I know, causing a resolution of the tumor. On the contrary, I am convinced that it accelerates its growth by the local irritation; and it causes a most vexatious complication of the case to the surgeon operating, as the testes are always adherent to these cicatrices, and often completely involved in them. The disease sometimes only attacks the penis,

the body, they can be detected in the blood by chemical reagents; but as yet we have no pathological reagents by which we can prove the presence in the blood of those pathological poisons, which evidently circulate in the blood long before they are deposited in the tissues. Professors Andral and Forget have detected encephaloid and tuberculous masses in the blood; but such cases are rare, and only occur in the last stages of a super-saturation of the system by these pathological poisons.

The evident tendency of modern pathologists is to discover pathological poisons in the fluids, when there is yet the possibility of eliminating them. Such is the direction of the labours of Dr. Frost and Dr. Bence Jones, of Professor Bennett and Mr. Quekett, and others; they do but continue the researches of the older humorists with a more advanced chemistry, and a new mode of investigation; and if they do so it is because they hope to find in the knowledge of the fluids the secrets of health and of disease.

which assumes the appearance of an elephant's trunk, hanging down to the knees, and ending in a wart bigger than a man's fist. But however fantastic or monstrous the shape may be, the penis is always found unchanged, and *in situ*; and in these proboscis-like productions it may be at once found, by cutting down upon a cane pushed up to the pubes, or, still better by slitting the tube up with a very long strong *bistouri caché* thrust up to the symphysis pubis. The operation for the removal of scrotal tumors, till of late, was considered so formidable, that few surgeons cared to deal with large cases; and Dr. Goolens, of the Medical College, Calcutta, who had considerable experience in this line, thus speaks of it, in Vol. viii. of the Transactions of the Medical and Physical Society of Calcutta:—

"It is clear that this operation is one of imminent danger, in which, hitherto, it has appeared that the chances for and against the recovery of the patient are evenly balanced."

The practical conclusions I have come to from 161 operations are—

I. That, so far from this being the case, the results are marvellously satisfactory, even when the tumors weigh 40, 50, 60, 70, 80, 90, 100lbs. and more, provided the operation can be got through quick enough,—in from three to six minutes, and in the mesmeric trance. In 161 operations for the removal of tumors, from the size of a man's head to 103lbs., the mortality has only been *five per cent.*; but in no instance has death been caused directly by the operation, or followed soon after it, but at the distance of many days, weeks, or months, in consequence of lock-jaw, fever, cholera, diarrhoea, and exhaustion of the system;—from what may be called hospital diseases, and accidents in the course of the cure; and this has been going on with all the regularity of a law of nature for the last five years.

II. That, when the constitution is good, the patient not above 40 years of age, and the tumor does not exceed 40lbs., or possibly 50lbs., it is quite practicable to save all the organs without much danger.

III. That when the age of the man and the size of the tumor exceed this, no attempt should be made to save the testes; because the patient will either bleed to death in the attempt, or, if not, he testes will be found to be useless

after all, and requiring to be removed. But, even supposing the patient to escape with his life, and the testes to be sound, his constitution would not be able to perform the process of covering them again; they would slough, and require a second operation for their removal, or the man would die exhausted in the effort at reparation, as we have more than once seen. I therefore never attempt to preserve the testes when the tumor is above 50lbs. (unless the man is strong and robust); but the penis, with one exception, has been always saved, however large the mass.

I will now present your readers with some illustrative cases, taken from the beginning, middle, and end of my practice, and will conclude with some practical remarks on the propriety or otherwise of administering chloroform in such operations.

The following is among the first mesmeric operations for this disease:—

Sept. 2d, 1845.—I was stopped on the road to-day, and requested to go into a temple to see a sick Fu Queen. On entering, I found a healthy-looking man of 60; but he was nearly blind from cataracts, and had a scrotal tumor of about 30lbs., weight, which he begged me to remove. I examined it, said I would consider of it, and then drove on to Chinsurah to see Dr. Ross, the surgeon in charge of the troops there, to whom I said, that if he chose to return with me I would endeavour to show him a mesmeric operation. He willingly consented; and, in passing the Fu Queen's house, we carried him to the hospital along with us. The cook of the hospital, one of my best mesmerisers, was set upon him, and in half an hour made him insensible. Considering the man's age, and the size of the tumor, we did not think it worth while to save the testes, and the operation was therefore very soon effected. The man never moved, and did not awake till after the last artery was tied. Seeing him about to awake, he was covered with a sheet, and asked, when he came to his senses, if he had been in any way disturbed in his sleep: he said "No." He was then desired to sit up and show the tumor, as I wished to examine it. He did so, and actually put his hands down to raise the mass as usual; and his look of amazement on missing it was something not to be forgotten.

Dr. Ross published an account of this

and other operations in which he assisted me.

Oct. 25th, 1846.—Gooroochurn Shah, a shopkeeper, aged 40. He has got a monster tumor, which prevents him moving: its great weight, and his having used it as a writing-desk for many years, has pressed it into the shape of a gigantic cooked hat. His pulse is very weak, and his feet oedematous, which will make it very hazardous to attempt its removal; but life is literally a burden with such an appendage, and he is willing to risk life for the chance of getting rid of it. Having no precedent to guide me, and knowing that expedition was his only safety, I determined to make it a case of decollation as much as possible, without attempting to save the penis even. He became insensible on the fourth day of mesmerising, and was drawn on the mattress to the end of the bed. Two men held up the mass in a sheet, extending its neck, and I took it off by a circular incision. The loss of blood was immense, and he immediately fainted, but recovered without great difficulty in a short time. After tying the last vessel, the mattress was again pulled back upon the bed with him upon it; and at this moment he awoke, and said that nothing had disturbed him. We had no time to spare, certainly; but I saw that the penis might have been spared, and in every subsequent case it has been so.

At the end of a year I reported to government that one hundred operations of all kinds had been performed by me in the mesmeric trance, without the patients knowing anything about it; and I offered to demonstrate the truth of my statement to any number of persons in whom the government had confidence. Upon this a Mesmeric Committee was organized by order of Sir Herbert Maddock, the Deputy Governor of Bengal, to witness and report upon operations to be performed by me before them. For this purpose I came down to Calcutta from Hooghly, and in the course of fourteen days performed seven mesmeric operations in the presence of the Committee; and this is the summary of the Committee's observations:—

"In all these cases, without exception, after the operation was completed, the patients expressed no knowledge or recollection of what had occurred, denied having dreamed, and denied having pain till their act"

rested to the place where the operation was performed."—(Mesmeric Committee's Report).

Among the operations performed before the Committee was a completely successful one of amputation of the thigh: but as this paper is devoted to scrotal tumors, I will proceed to the first very remarkable case that occurred after I came to Calcutta:—

A few days after the Committee had ceased to sit, a man came to the Native Hospital, where the Committee held their meetings, with an enormous tumor, and I put him under treatment.

Oct. 9th, 1846.—Horoondo Saha, aged 27, hearing that I was in Calcutta, came to the Native Hospital to-day with an immense tumor. It measured seven feet in circumference, and two feet round its neck. The disease began seven years ago with hydrocele, and its progress has been very rapid for the last three years. Although the tumor is actually as heavy as his whole body (he appears to be under 8 stone weight), his person is in tolerable condition, and his constitution does not seem much broken.

10th.—He was mesmerised to-day for the first time, for two hours, by two persons, taking one hour each. He slept profoundly, and was partially cataleptic. The best mode of managing the mass, described hereafter, was rehearsed without awaking him.

11th.—No mesmeric effects to-day, on account of his system being deranged by the periodic (?)* that very generally attends these tumors.

12th.—The mesmeric phenomena are less marked than on the first day. He is still feverish.

13th.—This day being excessively stormy I did not go to the hospital, thinking that the gentlemen interested in the progress of the case would not venture out in such bad weather. At 2 o'clock P.M. I received a note from Mr. Hume, a magistrate of Calcutta, and a member of the late Mesmeric Committee, informing me that the patient had that day exhibited the most perfect catalepsy, and that "I might have made minced meat of him."

14th.—The same appearances being present to-day, I proceeded to operate upon him. The tumor had been daily tied up in a sheet, to which a rope was attached rove through a pulley in a

* Omission in MS.

rafter. The penis was dissected out. The mattress was then hauled down to the end of the bed; his legs were held asunder, and the pulley was put in motion to support the mass and develope its neck. It was transfixed with the longest two-edged knife, which was found to be too short, as I had to dig the haft of the mass to make the point appear below, and it was removed by two semicircular incisions right and left. The flow of venous blood was prodigious, but soon moderated under pressure of the hands, the vessels being picked up as fast as possible. The mass, after half an hour, weighed 108lbs., and was as heavy as the man's whole body. During the whole operation I was not sensible of a quiver of his flesh. Dr. Duncan Stewart, Residency surgeon, and a member of the late Mesmeric Committee, held his pulse all the time, and had the best opportunities of observation: he has kindly furnished me with the following notes:—

Dr. Stewart's Notes.

"The time occupied in the operation was six minutes, including the application of ligatures to the spermatic arteries, and three or four other vessels that spouted. The arterial hæmorrhage was very small indeed, but the welling of blood at the moment of each transverse cut was appalling. The loss could not have been less than ten or twelve pounds. The patient remained throughout most perfectly still and motionless. I held his pulse the whole time, and counted it carefully. Immediately on the removal of the tumor it sank to zero; his face became pale, and cold sweat bedewed his forehead: it was not till his head was lowered that he recovered from the collapse caused by so sudden and great a withdrawal of vital stimulus from the heart and brain. The pulse gradually returned, and was found, when first counted, to be 120, very small, compressible, and intermittent, but there was not the slightest evidence of consciousness or pain.

"It was now found necessary by Dr. Taylor and myself to pour some wine and hartshorn down his throat; but, as he could not swallow in this state, it was allowed us to dash cold water in his face, blow in his eyes, and fan him; by which means he awoke from his trance, recovered sufficient sensibility to drink some brandy and water, and presently

subsided into perfect repose: the pulse, however, remained very weak, and settled at 100. The patient was then carefully removed to a clean bed: he passed a good night; the wound was stitched and strapped the following day; and, on visiting him this morning, I found him looking composed, and sleeping soundly, the parts looking well, and with every prospect of a most successful cure.

(Signed) "D. STEWART, M.D."

The operation was performed in a room full of spectators, including the Secretaries to Government, and many medical and unprofessional gentlemen. Although this operation was not performed before the Committee, it was ordered to be printed in their report by the Government.

The man is now well and fat.

On receipt of the Mesmeric Committee's report, which was printed by order of Government, the Deputy-governor determined to give me an experimental hospital for a year, which intention was thus intimated:—"So far has the possibility of rendering the most severe surgical operations painless to the subject of them been, in his honour's opinion, established by the late experiments performed under the eye of a committee appointed for the purpose, as to render it incumbent on the Government to afford to the meritorious and zealous officer by whom the subject was first brought to its notice, such assistance as may facilitate his investigations, and enable him to prosecute his interesting experiments under the most favourable and promising circumstances." (Letter of the Secretary to the Government of Bengal to the President of the Mesmeric Committee).

Forty-six capital operations were performed within the year in the experimental hospital; and, as the last operation has the novelty of having been performed by a native surgeon, I shall only give it,

Dec. 23, 1847.—Luckynaram Day, aged 37, mesmerised for the first time to-day. He bore pricking and pinching very well, and only a slight shiver of the skin took place when he was touched with a bit of live charcoal. He resisted all the usual means of demesmerising, but awoke instantly on having cold water squirted into his eyes.

4th.—Found deeply entranced to-

day: he was pricked and pinched with the same results as yesterday, and could not be roused by the loudest noises. Some sulphate of magnesia was put into his mouth with difficulty, as his jaws were firmly clenched, as usually happens. The tongue remained quite passive, and the mouth gradually closed again. His nose was also put into a bottle of carbonate of ammonia, and he inhaled the fumes like common air. Repeated attempts were made to mesmerise him: his eyes were rubbed, opened, and sharply blown into, without the least effect. He was at last awakened by his eyes being syringed with cold water; and the moment he came to his senses, he began to retch, and said that his mouth was disgustingly bitter—why, he could not tell.

5th.—In the same state to-day. This man was quite ready the first day, but the operation was put off at the request of some persons who desired to be present.

6th.—The operation was performed to-day by my assistant, Baboo Budurichanda, in the presence of Dr. Morat, and other gentlemen. The penis, having been first freed, an incision was made in the course of the right cord, which exposed a large hydrocele sac, on opening which a great quantity of bloody pus escaped. As this convinced us that the testis was useless, it was no farther sought for, but was removed with the mass, after the left one had been dissected out. The left testis was also found to be involved in a hydrocele; and, as the tunica vaginalis was much thickened and hardened, it was dissected off the testis and cord; all which he bore like a dead body. He was mesmerised a quarter of an hour after all was over; and, when asked, said he had slept soundly, without being in any way disturbed, and was as strong as usual. He could not be convinced that he had been operated on till the part was shown to him. On seeing it he was overjoyed, and begged me to pare down his legs in the same way, as they were both elephantoid.

Mr. O'Shaughnessy, Professor of Surgery in the Medical College, Calcutta, tells us that, since the discovery of ether and chloroform, "Mesmerism no longer deserves the serious consideration of the operating surgeon;" and this brings me to the question of the propriety of

administering chloroform in cases of large scrotal tumors. If my views are correct, they have a much more extensive application.

If chloroform is resorted to at all (and I very rarely require to do so), I see no reason to suppose that it will not be as successful in moderate-sized tumors as in amputations, &c. But in my last half-yearly report of the Mesmeric Hospital I asked:—

"Who would dare to remove scrotal tumors weighing from fifty to one hundred pounds, and, more, under the influence of any narcotic drug whatever? Not I, certainly; and I would earnestly dissuade any one from attempting it, or suffering it to be done to him. We all now knew that chloroform has a tendency to paralyse the heart, lungs, and brain; and it requires for doctors learning to be convinced that such exhausting operations can only be performed with a chance of success in cases where the vital powers are intact. When these tumors weigh above forty pounds, the loss of blood is so profuse that the pulse is usually extinguished on the spot, and it takes a considerable time to revive it; the brain is so exhausted by the sudden withdrawal of blood, that the patient generally faints, and awakes in a half delirious state, and, the stomach sympathising, vomiting also takes place, and hours elapse before the equilibrium of the sanguineous and nervous systems is re-established.

"In the last tumor of four pounds I ordered the solid clots to be gathered, and they weighed two and a half pounds; and, taking into account the serum on the floor, with the blood in the mass, I presume that about five pounds of blood were lost in as many minutes; and we have seen that Dr. Stewart estimated the loss of blood at ten or twelve pounds in the monster tumor.

"It must be evident to every one that persons fainting from this immense hæmorrhage would probably (rather certainly) never revive if the vitality of the heart, lungs, and brain, was lowered by any additional influence whatever."

A girl lately died at the Medical College here a few minutes after the extraction of an eye; and Mr. O'Shaughnessy, the operator, made the following remarks upon the case:—"The unfortunate result in this instance I am dis-

passed to attribute entirely to the insensibility produced by chloroform. The loss of blood was trifling, the time occupied by the operation was short, and there was no important organ implicated by the removal of the diseased parts. The child fainted; and, owing to the general insensibility, the attempt at reaction was imperfect, asphyxia followed, and she expired."

But, though *fainting, asphyxia, and death*, followed the administration of the chloroform, we are plainly told by Mr. O'Shaughnessy that this valuable drug possesses "no poisonous properties!" Mr. O'Shaughnessy more truly says afterwards, however, "that all narcotic drugs are open to the objection that they prevent the reaction necessary for recovery from injuries attended with great exhaustion of the system." Dr. Goodeve, who, as he told me, has known and believed in mesmerism for the last twenty years, and fully appreciates its practical and philosophic interest, on seeing me remove a seventy-pound tumor lately under the mesmeric influence, said, on witnessing the state the man was reduced to, that, if there had been a drop of chloroform in the man's blood, he would never have breathed again. In the very last operation on a worn-out man of fifty (weight of tumor eighty pounds), I emphatically pronounced him *dead*, although the operation was performed in two and a half minutes. He at last gave a gasp, however, and in ten minutes was out of all danger, and is about to quit the hospital. Does any one believe that this man would have ever gasped again if his blood had been saturated with chloroform, or his vitality in any way depressed? Mesmerism is not open to the same objections; *for it not only protects, but exalts the nervous system*, as we know from extensive experience both in medical and surgical cases.

My warning against the use of chloroform in large tumor cases no sooner reached Madras than, as if to establish my character of a true prophet, we immediately heard of a fatal case there; and the occurrence of another at Alexandria goes to confirm my predictions. I would on no account be aiding and abetting in giving chloroform in monster cases of scroval tumors, being convinced that the patient, if he cannot be

mesmerised, has a better chance of life if operated on in his natural state. In one case of eighty pounds, the man could not be affected by mesmerism, and I removed the mass in his waking state: he recovered very well. In another refractory case of fifty pounds, in which all the organs were sound, I would not give chloroform, and the man did perfectly well.

Calcutta, May 6th, 1850.

** Want of space has compelled us to omit from this paper some passages which appeared to us to have no immediate relation to the subject, as well as the long list of operations and the large accompanying illustration.

HYDATID DEGENERATION OF OVUM. BY DR. PUTNAM.

THE subject of this case is a young married woman. Her last child born three years ago. Menstruation since that time regular. Last menstruation occurred during last week in November. During the following three months, suffered from pain in the back, bearing down, and copious leucorrhoea. There was also an unusual degree of chilliness, which made warmer clothing necessary. The above symptoms were aggravated at the periods of expected menstruation. She was positive that she was not pregnant, because her sensations were different from those she had usually experienced during gestation.

On examination, at the end of the second month, the body of the uterus was decidedly enlarged. No special change in the neck. At the end of the third month the enlargement was found to have subsided. On the fifteenth of March—at the middle of the fourth month—hæmorrhage occurred, at first very slight, but gradually increasing and attended with pain until the twenty-third, when the hydatids were discharged. Hæmorrhage continued more urgently until checked by the use of ergot, but did not entirely cease for three weeks.

The hydatid cluster would more than fill a half-pint bowl, the separate vesicles being of various sizes, from a pin's head to half an inch in diameter. The usual term hydatid has been employed; but it is well known to be a vesicular disease of the ovum, resembling hydatids only in external form. In this case no fetus was detected, but the deciduous membrane was perfectly distinct.

MEDICAL GAZETTE.

FRIDAY, SEPTEMBER 12, 1860.

WITHIN the last few years there has sprung up what appears to us to be a novel and dangerous interpretation of the law regarding charges of manslaughter brought against ignorant pretenders to the healing art. It has been long an admitted principle of law that the possession of a diploma confers no privilege, and that whether a man be a blacksmith or a fully qualified practitioner, the same rule is applied to determine the degree of criminality when death is caused by the ignorant or unskilful administration of medicines.

A new view of the law, and one which we believe to be most dangerous to the public, was, however, taken by Mr. Baron Alderson at the Liverpool Lent Assizes. In the case of the Queen *v.* Winterbottom, indicted for manslaughter, the learned judge is reported to have said, "The question for the jury to consider was, whether the prisoner had done what *he considered most advantageous* for the recovery of the patient? If he had done so, he ought not to be declared guilty of manslaughter. Unless the prosecutor made it plain that he was *not doing his best*, there was an end of the case: and if people employed unqualified persons to dispense medicines, they themselves must take the consequences." We had hitherto thought that one great object of law in a social state was to protect people from the results of ignorance and unskilfulness in cases in which they are incompetent to protect themselves. An uneducated man pretends to a knowledge of physic, promises largely, and prescribes an over dose of medicine, which kills his dupe, who has had no means of testing the validity of his pretensions, or ascer-

ing whether he was or was not qualified to practise medicine. According to this view of the law, no criminality would attach to such a person. It is most likely that the quack did what he thought was most advantageous for the recovery of his patient. The prosecutor cannot show that he was *not doing his best*; hence, according to Mr. Baron Alderson, the charge of manslaughter could not be sustained. These unlicensed practitioners of medicine destroy lives—not that they designedly adopt methods of treatment least advantageous (in their judgment) to the recovery of patients; not that they do not do their best; but because they use means of the proper and safe employment of which they are wholly ignorant. It is not, therefore, so much a question of *bona fides* as of ignorance, unskilfulness, and incompetency. If Mr. Baron Alderson's dictum be correct,—under what circumstances can an unlicensed and ignorant practitioner ever be convicted of manslaughter by the improper administration of medicines? We assert that it is equal to legalizing manslaughter at the hands of quacks. A man may prescribe a strong dose of aconite for another, and thus kill him. Any medical practitioner acquainted with the properties of this vegetable would know, *a priori*, that death would be just as likely to follow as if a loaded pistol had been discharged at the head of the patient. The new test for criminality, however, is, Did the prescriber consider that *he* was adopting a plan of treatment most advantageous for the recovery of the patient? Was he not doing *his best*, although that best involved the worst consequences for his patient? But then the learned judge throws out this piece of consolation to the public. If a person will employ an unqualified individual to prescribe aconite or hemlock for him, he must take the consequences! There is no giving it; this lies in

another man being foolish enough to take it at the recommendation of a person, before he has searched the lists of the different colleges in Great Britain to determine whether he is or is not qualified to practise.

In all other cases except physica, the *bona fides* of the pretender to a particular art, science, or mystery, avails nothing. Take the case of a man not licensed by the Trinity House to act as a river or coast pilot. He has perfect confidence in his own nautical abilities. In a difficult piece of navigation, he takes a course which he believes to be most advantageous for the security of the vessel: he runs the ship on a rock, and causes the loss of twenty or more lives. Would the conviction of such a person for manslaughter rest upon the bare fact, whether he was or was not doing *his best* at the time of the occurrence? If he was, then, according to Mr. Baron Alderson's law, there would be an end of the case. If the captains and crews of ships will employ unqualified persons to act as pilots, they must take the consequences. Let us test this principle by the recent case of the *Orion*. The mate who ran the vessel on the rocks of the Scotch coast did not take this fatal course with malicious intention: it was a course which he considered most advantageous for the vessel; he did his best; but he lost the ship, and with it many lives. According to the law of Mr. Baron Alderson, the mate, it appears to us, could not, under these circumstances, have been fairly held responsible for the fatal results. If passengers will embark on board of steam-vessels in which the captains and mates are unqualified to navigate them, *they must take the consequences.**

* The captain and second mate of the *Orion* were properly convicted, in the recent trial at Edinburgh, of causing death by neglect and unskillfulness. The exculpation of these persons from a charge of manslaughter was not made to rest on whether the mate had done *his best*, and

We do not think we have exaggerated the results to which this view of the law regarding manslaughter from the administration of medicines must lead. Our belief is, that it would not meet with the concurrence of the other learned members of the Bench. It is, however, exerting a pernicious influence, inasmuch as it is now quoted as a reason for the acquittal of every quack who is charged with manslaughter in poisoning another by an over-dose of some dangerous medicine. It was thus recently brought before a jury at Carlisle in a case recently noticed in our pages,* and no doubt influenced their verdict of Acquittal. With the dictum of Mr. Baron Alderson, and with the numerous acquittals before us, where there could be no doubt whatever that death was entirely owing to ignorance and unskillfulness, we may reverse the old adage, and proclaim, SALUS POPULI NON EST SUPREMA LEX.

PHYSICIANS AND APOTHECARIES.

At the late meeting of the Pennsylvania State Medical Society, among the many resolutions offered we find the following:—“Whereas it is asserted and confidently believed by a portion of the public that it is the practice of some physicians and apothecaries to enter into a collusive arrangement, by which the former are to receive a per centage upon all prescriptions sent to the latter, and in this way bring dishonour upon the medical profession: therefore Resolved,—That this Society regards all collusion between physicians and apothecaries, whether with a view to peculiar profit or patronage, as opposed to every principle of that moral code which the profession have adopted; and that no physician known to be guilty of such a collusion should be entitled to the confidence and professional intercourse of medical men.”—*Boston Medical Journal*.

whether he had taken that course which he thought most advantageous for the safe navigation of the ship! On these points there would have been a verdict in his favour. We quite agree with our contemporary the *Times* in the opinion that, had these men been tried by an English instead of a Scotch jury, they would have been acquitted, or, if found guilty, discharged with a reprimand and a caution to take more care at another time!

Reblets.

Annales d'Hygiène Publique et de Médecine Légale. 1850. 1. *Sanitary condition of buildings for the poor.* 2. *Railway Accidents.* 3. *Bread.* 4. *Child-murder by blows on the head.* 5. *Compound poisoning.*

1. In the April number of the "Annales," the department devoted to medical police opens with a paper by M. Villermé, on the subject of *cités ouvrières*, or erections on the plan of the model dwelling-houses of the London "Society for the Improvement of the Labouring Classes." Such schemes for the elevation of the condition of the lower orders in towns have of late been occupying the public attention in France, Belgium, Hanover, and Prussia. Several establishments of this kind have already been opened in Berlin; and one is in course of erection in Paris. M. Villermé deprecates the form which these structures have assumed with us, and advises that of a series of small separate houses, along the side of a street, in preference to single barrack-like buildings; and with this the reports from Prussia agree. For reasons which, unhappily, are but too applicable to the majority of continental workmen, he proposes altogether to exclude unmarried persons from such establishments, in order thereby to avoid the risk of having them speedily converted into foci of turbulence, or nests of sedition.

2. This paper is followed by a report to the Council of Health of the Northern department of France, from a mixed commission, on the best means of lessening the number of accidents from the employment of steam as the motive power in manufactures and trades. The steam machinery in Lille, the great industrial centre of the North, gives occupation to 8170 work-people, about one half females, and one-sixth children. Amongst these, from the returns of three years, the commissioners calculate the annual number of accidents at 12·5 for every 1000; of which 10 are curable, 1·25 fatal, and 1·15 (1·25 ?) are found to involve the loss of one or more limbs;—an average which we must regard as a high one, when we consider that in 1840 the deaths by machinery, of all kinds, for the population of England,

only amounted to 00·94 in the 1000 (vide Sixth Annual Report of the Registrar-General).

The preventive measures recommended by the commission are confessedly the same as those which our own legislature has made imperative on the owners of silk, cotton, and woollen mills in Britain, in the Factory Acts of 1844 (7 Vict. cap. 16), in which, for once at least, where the public safety is concerned, we can reverse Sterne's boast, that "they manage these things better in France."

3. The paper which comes next is the conclusion of a report continued from the previous number, which embodies the labours of a commission of the Council of Health of Paris, appointed by the Minister of Commerce, for the purpose of determining the quantity of bread of the different sorts which a sack of flour should yield to the baker.

By the present communication it appears, that from the early part of the fourteenth century downwards, several successive administrations in France have instituted inquiries into this matter, with the intention of thereby legislating for the public interest, although without arriving at any very satisfactory results. Nor has the commission in question been altogether successful, having failed in coming to a unanimous conclusion on the principal point referred to its decision. As was, perhaps, to have been expected, the experiments undertaken by the commissioners were found only to yield them approximative results, while they showed conclusively that the yield of bread from a given weight of flour will vary usually with circumstances;—such as the quality of the flour itself; the relative proportions of gluten and starch contained in it; its hygrometric state; the amount of water employed in the working of it up; the temperature of the oven, &c.; and all this, independently of the loss in the transport of the article, and from the mixing of the different sorts essential to the manufacture of bread of good quality. The size and shape of the loaves have also been shown to affect considerably their ultimate weight.

Two other papers complete this portion of the Annals—the first on the insalubrity of rice fields; the other commences an inquiry into the effects of copper and its alloys on the health of the workmen employed in their fabrica-

tion. To this last we shall return when we have the completion of the inquiry before us.

4. The department of the journal appropriated to medical jurisprudence commences with an instructive narrative, by M. Orfila, of the proceedings originating in the case of the suspected murder, from blows on its head, of a female infant of three years, by its mother, Elizabeth Prat, or Sarret, at La Rochelle.

The infant, born before marriage, was known to have suffered much harsh treatment from its mother, who had denied it the ordinary comforts of life. Its death took place on the 9th of August, 1849, after an illness of thirty-three days, (during which it had no regular medical or other attendance), and was attributed to violence, on the part of its mother, on the 7th of the previous month. This woman, when judicially examined, ascribed the death of her child to the effects of an accidental fall from a child's chair, when it struck its head against a stone floor, the seat of the chair in question being 21 centimètres (8·267 inches) in height. The leading symptoms of the illness, as described by her, were occasional acute pains in the head, nearly constant stupor, irritability of stomach, and loss of power over the bladder. A woman who had seen the child during life had drawn the mother's attention to an unusual softness of the occiput.

On the 30th of August the body was disinterred, and inspected by MM. Chesnet, Meyer, and Gaudin, one of whom had visited the infant before its death. The corpse was considerably attenuated, and decomposition had made some progress. The head was inclined to the left side: the cranial bones were unusually moveable: over the parietal, and a part of the occipital bones, the scalp was thickened, softened, and infiltrated with a blackish fluid. There was a vertical fracture of from six to seven centimètres (2·36 to 2·75 inches) in length on the right side of the occipital bone, without any corresponding injury of the scalp: the brain was a dark, fetid pulp: the dura mater, which was uninjured, was deeply coloured in its interior over the whole of its left side.

The report of the inspectors was favourable to the accused. The condition of the abdominal viscera, which

were natural, negatived the charge of starvation. The appearances about the head were, they conceived, as likely to have been caused by a fall as by a blow. The fracture of the occiput was, in their opinion, indirectly the cause of the child's death, by giving rise to effusion of blood, and consecutive inflammation of the brain, the symptoms attending which tallied with the mother's statements.

On the case being subsequently referred to the same parties separately, for further consideration, and their attention having been called to a point which it seems they at first had overlooked, their evidence came to disagree to some extent. M. Meyer stated, that while the injuries on the child's head were not cadaveric, but the effects of direct violence during life, they were as likely to have been caused by blows as by a fall. The injury in the occipital bone he considered to have been a counter-fracture. On examining the skull, both with and without a lens, he found that portions (of the outer surfaces?) of the left parietal, and of the left side of the occipital bones, had lost their natural smoothness and polish, which he attributed to the effects of disease. M. Gaudin's opinion was so far different, that while he agreed with M. M. that the occipital injury was a counter and not a direct fracture, he was positive that it could not have been caused by a fall from the child's chair, and considered that the roughness of the bones on the left side of the skull had been the effect of violence, such as a blow or fall on the head. M. Chesnet, who, in doubts of his own competency to form a correct judgment, had, in the interim, seen and consulted with MM. Orfila, Velpeau, and Roux, in Paris, now deposed that he found a difficulty in admitting a fracture of the occiput by a counter-stroke, and that the loss of polish of the parietal and occipital bones was most likely a purely morbid change.

In these circumstances the legal authorities requested the opinions of MM. Orfila, Roux, and Velpeau, on the leading points in the case. These gentlemen did not, however, coincide in their views any more than the local practitioners. Thus, while Roux and Velpeau viewed the occipito-parietal lesions on the left side of the head as merely cadaveric, and as the effect of putrefaction, Orfila's opinion was, that they had been produced during life. Again, Roux and

Velpéau decided that the occipital fracture had been caused by a direct blow or fall on the part, and not by a counter-stroke; whereas Orfila thought it by no means impossible that forcible violence applied to the left side of the head would have fractured the right side of the occipital bone. Once more Roux and Velpéau considered that the fracture might have been occasioned by the fall, and in the circumstances indicated by the accused; while Orfila could hardly admit that it could have resulted from so slight a cause.

At the trial in February last Sarret was acquitted.

In the remarks which he has appended to the case, Orfila contends that, from the circumstances adduced on the trial, the injuries on the head of Sarret's child could not have had an earlier date than the 30th of July, and that his positions in opposition to his colleagues are thus very much strengthened.

One or two points in the above narrative appear to us to call for a passing comment. The softened and infiltrated scalp, and the dyeing of the dura mater in a body twenty days buried, and in the month of July, are but equivocal tokens of the mode in which the injuries on the left side of the child's head were produced, and far more so of the period when they originated, whether during life or after death. But if we connect with these appearances the change which the bones had undergone on the same side of the head, we are led to refer the whole to the effects of disease, in part at least, if not entirely. We cannot, certainly, admit, with some of the witnesses, that a degree of roughness (un chagrinement), and a loss of polish (un dépoli) of the cranial bones, visible to the naked eye, could be produced by putrefaction alone. The opinion of Orfila, running counter to that of his two eminent colleagues and one of the provincial reporters, to the effect that the fracture at the occiput could hardly have resulted from a mere fall of eight inches, especially when we are aware that no additional impetus was communicated to the body in falling, is undoubtedly in harmony with the teachings of experience without a single exception. We are, however, compelled to differ from this veteran medical jurist when he assumes that the fracture might have been a counter one. The question here mooted as to the likelihood of violence

to the head of a child giving rise to a counter-fracture of the skull, appears to us to be a new one in legal medicine, and one which leaves room for difference of opinion, in the entire absence of facts in our surgical works bearing directly on this point. But the very silence of surgical writers on such an occurrence as counter-fracture of the cranium in children, seems to us strongly hostile to Orfila's decision, and to favour that of his opponents. Besides, the flexible character of the infantile skull, and the unfused state of its separate bones, must be considered as highly unfavourable to the transmission of such an impulse from one side of the cranial vault to the one opposite to it as takes place in the production of counter-fractures. Chaussier's experiments, where direct fractures only were produced on dropping dead children from a height of eighteen inches, point in the same direction: and we may be permitted to add to the same purport, in so far as it goes, the fact, that in ten cases of fractured cranial bones, resulting from blows or falls in persons under puberty, which we have had occasion to examine, each was found to have been a direct fracture.

5. Passing over a discussion on the legality or illegality of omitting to register the births of still-born infants,—a point on which there have been of late, in France, some conflicting legal decisions,—we come to two cases of compound poisoning. The first of these is a mere notice to the following effect;—viz. that a person was tried and found guilty of the crime of poisoning a female child with alum and sulphate of iron, at Toulouse; and that M. Filhol, professor of chemistry there, detected in the matters submitted to him for examination a sufficient quantity of these substances to have caused the infant's death. The other case is one of alleged poisoning, tried at the Orne assizes, in July, 1849. The deceased, a labourer, died in four days with all the symptoms of irritant poisoning; and after seven months' interment, M.M. Chevallier and Lassaigue procured 0·21 grammes (8·26 grains) of arsenic from portions only of the stomach, liver, kidneys, and intestines, forwarded to them. The man's wife and paramour, besides being charged with administering arsenic to their victim, were also believed to have given him a few weeks before his death a quantity

of a substance sold under the name of "phosphoric paste for destroying rats," and which Chevallier and Lassaigue discovered to be a preparation of ordinary phosphorus diffused through flour paste. This substance seems, however, to have occasioned but a temporary illness, though the remains of the soup in which it had been administered, when thrown out, had destroyed some fowls who had eaten it.

The accused parties were acquitted by the court, but on what grounds we are not informed.

Amongst the "varieties" at the end of the journal we find a very instructive analysis, by M. Briere de Boismont, of the report of a commission lately appointed by the king of Sardinia for the investigation of the subject of cretinism as it exists in that country.

Descriptive and Illustrated Catalogue of the Histological Series contained in the Museum of the Royal College of Surgeons of England. Volume I. Elementary Tissues of Vegetables and Animals. 4to. pp 305; 18 Plates. London. 1850.

The medical profession are under deep obligations to the Royal College of Surgeons of England for having collected a most excellent library of medical books, and for having, by their fostering care, raised the Hunterian Museum to be the most noble establishment of the kind the science of medicine can boast of.

By the application of the microscope to anatomy and physiology, the domain of these sciences has of late years been much extended. A museum of large objects only being, therefore, no longer a complete exposition of their present state, the Royal College of Surgeons have wisely and liberally created a microscopical department in the Hunterian Museum. The nucleus of this was a few preparations made by Mr. Hewson, originally belonging to Mr. John Hunter, and some purchased a few years ago from the executors of the late Dr. Todd, of Brighton. By the addition of Mr. Quekett's valuable collection, and by presents from various sources, the series has now become, under the auspices of Mr. Quekett, very extensive, and may be considered invaluable.

All the great facts in the minute structure of vegetables and animals are

bodily presented in the bare and simple severity of nature.

To Mr. Quekett, and to the liberality of the Royal College of Surgeons, who have enabled him to carry on his scientific labours, the sciences of anatomy and physiology are thus especially indebted.

The present illustrated catalogue, prepared by Mr. Quekett, descriptive of the results of a part of these labours, will be particularly acceptable to those who, living at a distance, have not the opportunity of directly examining the microscopical collection. The pictorial illustrations may be almost considered as duplicates of the principal preparations.

Report of the Committee of Internal Health on the Asiatic Cholera; together with a Report of the City Physician on the Cholera Hospital. 8vo. pp. 180. Boston. 1849.

This report opens with an account of the very efficient sanitary measures actively put into execution by the municipal authorities of Boston previously to and during the visitation of the cholera in 1849. Among the first steps taken were the fitting up of a cholera hospital, and the organisation of a medical staff for domiciliary visitation. The description given of some of the worst localities of Boston will prove the need of these sanitary measures. Several woodcuts exhibit courts and alleys, and places of the most wretched condition, as the residences of American and Irish human pigs.

From the 29th of June to the 15th of November there were under treatment in the hospital two hundred and sixty-two patients: of these, one hundred and sixty-six died. The opinion of the medical officers of the hospital was against the contagious nature of the cholera. With regard to treatment, we find the same statements as are contained in every other report, that all depended upon the early use of remedies: of these a list is mentioned, with the commentary upon each that it was *useless*! The pathological changes found after death were carefully noted in thirty-three cases, and presented the same morbid appearances that have been observed elsewhere.

We consider this Report as a useful contribution to the facts of which the history of cholera consists, and as a

document which will doubtless be of service on some future occasion.

Remarks on Epilepsy, or Puerperal Convulsions. By GEORGE KING, Esq. Pamphlet, pp. 16. Worcester: Deighton. 1850.

THIS is a reprint, from the Provincial Medical and Surgical Journal, of a paper in which the author shows that puerperal convulsions are more frequently the result of "mental impressions and uterine irritability than of active congestion of, or determination of blood to, the brain; and, therefore, that the abstraction of large quantities of blood in such cases is highly injurious, and more calculated to destroy the energies of the system than to restore or to relieve them." We fully concur in the author's views. We have met with many cases of puerperal convulsions in which depletion would have inevitably aggravated symptoms which were relieved by an opposite plan of treatment.

Mr. King's pamphlet, though short, is to the purpose, and on both accounts merits perusal.

Every-day Wonders; or, Facts in Physiology which all should know. 12mo. pp. 137. Van Voorst. 1850.

THIS is a novel attempt to convey a general knowledge of the structure and physiology of the human body to the mind of a child. The facts are well selected, and put in such a form as to be adapted to the capacity of a child under the guidance of a teacher. All technicality is avoided, and the chapters contain anecdotes bearing on the subjects to which they refer. The descriptions are made clear by engravings on wood. Some may object that it is absurd to attempt to teach a child such subjects; but, whether expressly taught or not, children grow up with some loose ideas respecting the uses of a heart, lungs, stomach, and liver. This little volume does not attempt too much, but it has the excellent use of giving correct views of physiology; and it will thus serve to prevent the growth of false and erroneous ideas in the youthful mind. We recommend it as a useful and instructive book for children.

Introductory Lecture to a Course of Military Surgery; delivered in the University of Edinburgh, May 1st, 1850. By SIR GEORGE BALLINGALL, M.D., F.R.S.E., Professor of Military Surgery in the University of Edinburgh. Pamphlet, 8vo. pp. 8. Edinburgh. 1850.

Hospital; an article written for the Cyclopædia of Practical Surgery. By SIR GEORGE BALLINGALL, M.D. &c.

THESE papers contain much interesting information; the former more especially with reference to the history of military, the latter with regard to that of civil hospitals. In the last-named of these two pamphlets the reader will find very full and judicious observations on the construction of hospitals, and on their internal arrangements and general economy. We trust that Sir George Ballingall's suggestions will receive from the founders and architects of hospitals that attentive consideration which they fully deserve.

CASE OF POISONING BY CORROSIVE SUBIMATE. BY B. W. MCCREADY, M.D.

THE patient was a young woman, who swallowed about 3 oz. of a solution of corrosive sublimate of the strength of one drachm of the salt to the pint of alcohol, and had consequently taken about 22 grains. The case, according to Dr. M'C., is worthy of note for the following reasons:—

1st. The general symptoms bore no relation to the amount of local disease. After the first few hours the pulse was moderately full, and not above 90, and the temperature not unusual. This might be connected with the state of the blood after the occurrence of the suppression of urine; but it was present previous to the coming on of the suppression.

2d. The amount of inflammation and ulceration of the large intestines was such as occurs commonly with severe dysentery, and yet the dysenteric symptoms were slight, much slighter, indeed, than commonly occur in cases of poisoning by corrosive sublimate.

3d. Suppression of urine continued from Monday until Saturday, the day of her death, and yet the patient retained her senses, and was easily roused, exhibiting no signs of cerebral disturbance except slight drowsiness and some tendency to wandering.—*New York Journal of Medicine*, July.

Proceedings of Societies.

BIOLOGICAL SOCIETY OF PARIS.

Monthly Summary, May and June 1880.

Existence of a Rhythmical Movement in the Crop of Birds.

M. BROWN-SEQUARD stated that he had observed a regular rhythmical movement in the crop and oesophagus of birds, and that these movements become more energetic when the bird is asphyxiated. The average normal rate of movement is from ten to twenty in the minute.

Pathological Anatomy.

M. BOUCHUT related the particulars of a case of osteosarcoma of the pelvis occurring in a woman forty-two years of age, which had run its course to a fatal termination in four months from the first appearance of any symptoms. The effects were manifested in the interruption to the functions of the lower extremities proceeding from implication of the structures of the hip-joint.

M. GUBLER detailed a case of intra-cranial encephaloid tumor. The chief symptoms were hemiplegia, with contraction of the limbs. The tumor, of the size of a hen's egg, was seated in the middle lobe of the right hemisphere of the brain.

M. MAZIER related a case of fibrous tumor of the cerebellum, producing convulsive movements and paralysis on the side corresponding to the seat of the tumor.

M. DAVAINÉ related a case of compression of the thoracic portion of the oesophagus by a tubercular mass in the posterior mediastinum of an Ape.

M. VERNEUIL presented two specimens of abnormal *diverticula* attached to the intestines.

Malformation of the Hands.

M. GUBLER exhibited a plaster-cast of a hand presenting a deficiency of the last phalanges. The fingers were united by a web-like extension of the integuments.

On Hematozoa.

M. FILLON stated that he had detected *filaria* in the blood of nine individuals of the *corvus frugilegus*. They presented the aspect of minute elongated filaments slightly flattened at their extremities, one of which was more rounded than the other; but an anterior and posterior extremity could not be distinguished. Their transparent bodies exhibited no trace of internal organization. These *filaria* were found in the heart and large vessels.

M. FILLON regarded them as the young of the *strongylus* met with in the stomach, liver, and lungs.

Anencephalic Fetus.

M. OLIER transmitted the description of an anencephalic fetus in which spina bifida also existed through the whole length of the canal. The spinal cord was flattened and bifurcated at its superior extremity; the spinal nerves were not in connection with the cord; the limbs were well formed; the weight of the fetus was from three, to three and a half pounds; the neck was entirely wanting, and the small head was attached to a depression on the trunk; the thorax was well formed; the lower jaw, which was disproportionately large, extended to the epigastrium; the nose was short; the eyes closed, and the globes directed upwards; these were extremely small, and unprovided with retine; the upper part of the head was wanting from above the orbits, and was replaced by a fibrous membrane, extending backwards to the trunk at the third lumbar vertebra; the viscera were normal as to structure and position. No motion or sign of life was manifested by this fetus after birth, although they had been felt previously.

FATAL CONSEQUENCES OF AN APPARENTLY SLIGHT INJURY TO THREE FINGERS OF THE LEFT HAND. BY DR. KRAMER, OF ASCHERSLEBEN.

A YOUTH, aged 12 years, had his hand crushed by a piece of wood falling upon it from a cart as he lay upon the ground, having just before fallen down.

The last joint of the index, middle, and ring fingers were much crushed, the nails nearly detached, and the capsular ligaments of the second and third phalanx of the middle finger ruptured. The fingers were carefully bandaged, &c., and the patient directed to apply cold water, and attend daily on Dr. Kramer.

Such accidents as this are of common occurrence, and in most cases the cure is complete in two or three weeks, with, at the worst, the loss of the nail, and perhaps the last joint of the finger. The prognosis to this effect was here given. For a few days the case went on well; the nails of the index and ring fingers were detached, the febrile reaction was moderate. Granulations took place as in ordinary cases.

Things did not go on so well, however, with the middle finger. The last joint became gangrenous. The finger was amputated, but the gangrene extended.

Nine days after the receipt of the injury he felt pain in his neck. On the following day tetanus manifested itself, and he died two days later.—*Casper's Wochenschrift*. x

Hospital and Infirmary Reports.

KING'S COLLEGE HOSPITAL.

*Case of Lithotrixy—Stone of large size—
Steele symptoms after operation—Death.*

AN operation for crushing the stone is one which is now so frequently put in force, that an ordinary case of this nature would hardly be worthy of special report; but it happens every now and then that circumstances arise, in connection with the operation of lithotrixy, which change this mode of treatment from a somewhat simple and easy process into a complicated and difficult affair. Under such circumstances, he who carefully watches a case of lithotrixy from beginning to end, or who in any other way makes himself acquainted with its particular features, will gain most useful instruction.

We have selected for this report a case of stone in the bladder, in which lithotrixy has been performed by Mr. Fergusson, and which will afford both instruction and interest. The case is as follows:—The patient, a stout man, aged about sixty, came into hospital, at the last week of June, with symptoms of stone in the bladder, from which, in a somewhat severe form, he had suffered for several years. It was never discovered, however, that he had a stone, until Mr. Fergusson examined him, when it was readily detected. Mr. Fergusson considered the calculus to be of considerable size, and thought it probable that there were more than one present. There was no stricture of the urethra, and no irritability of the urinary passages when the sound was used, and there was no evidence of disease of the bladder. Under these circumstances, then, Mr. Fergusson deemed it proper to attempt the operation of lithotrixy, although the stone was doubtless of considerable size; yet as the parts were so little sensitive, he considered it a fair case for that mode of proceeding which must be looked upon as giving the patient less hazard than that of lithotomy.

Consequently, on Saturday, June 29th, the patient was put under the influence of chloroform, and the stone, which was evidently of considerable size, was without difficulty broken up; Mr. Fergusson using a modification of that most simple and effectual lithotrite worked with the rack and pinion.

On the following day the patient had much pain and difficulty in passing his water; several fragments came away, but with difficulty and irritation; he was ordered opiates and fomentations.

On the fourth day, July 2nd, he was suffering terribly, being continually seized with the desire to pass his water, which came away with excessive difficulty; and it was evident that it was hindered from passing by a piece of calculus blocking up the urethra. He had obtained no rest, and was in a high state of febrile excitement; his skin being hot, his tongue covered with a thick white fur, and his pulse running upwards of 120. He also complained of great tenderness at the lower part of the belly. Mr. Fergusson at his visit passed a catheter down the urethra; but it was stopped about the membranous portion by fragments of stone sticking there: he endeavoured, as far as he was justified, to push them back into the bladder, and thus relieve the man from the retention he was evidently suffering under; but after a cautious trial he was foiled. He then introduced the straight instrument with three blades for the removal of fragments from the urethra, and by this means, after some long and patient manipulation, he was enabled to remove a considerable quantity of broken-up fragments which had conglomerated together, and thus hindered the free passage of the urine. A catheter was now passed, and a considerable quantity of bloody and ammoniacal urine drawn off, to the great relief of the patient. He was ordered to have hot fomentations, with laudanum, and to take a morphia draught at night time. On the next day he was much easier, although he was troubled still with a frequent desire of making water, which comes away with difficulty: he has passed more fragments.

At Mr. Fergusson's visit on the 4th he was still suffering somewhat, but not nearly to the extent that he had been; he could pass his water with more freedom, and the febrile excitement was not so great, and he did not complain of pain in the abdomen. Mr. Fergusson did not use any instrument. The patient continued to suffer a great deal of inconvenience from the irritability of the urinary passages, and the pain which the fragments of stone produced in their way through the urethra. On the 7th he passed a very large and rough fragment, which caused great pain.

On the 9th he had passed a very good night previously, from the opiate which he had taken; but when Mr. Fergusson visited him he was suffering greatly from pain and irritation, and there was considerable difficulty in passing water; the pulse was 120; tongue still much furred; appetite bad. A catheter was passed down the urethra, but was again stopped by fragments of calculi sticking. Mr. Fergusson therefore used the urethra forceps and extracted them, and afterwards drew

off some urine. Chloroform was then used, and the lithotrite was introduced, and more of the stone broken up: he was ordered a warm bath.

15th.—This poor man has been suffering very much since the last report; some small fragments have passed away from him, but not many; he still has great irritation of the bladder and urethra, and his urine comes away with difficulty. His general condition is very bad; he has lost flesh, and has become very feeble; his pulse amounts to 120, and is weak; tongue very much coated with a dirty fur; appetite very bad; takes only fluid nourishment, in the shape of beef tea, &c.; he has been ordered some gin and water, which he relishes, and which gives some relief to the irritability of his urinary organs. He gets sleep at night by powerful opiates, but he is delirious at times.

16th.—Mr. Fergusson, at his visit to-day, finding that no fragments were coming away, and that the man was suffering so much from their retention, had him placed under the influence of chloroform, and injected the bladder with tepid water: this viscus was in a very irritable condition, however, and the injected fluid was repelled immediately, and it was found necessary to inject more, and compress the urethra, thus preventing its exit. The lithotrite was then introduced, and several fragments were broken up: the patient was ordered to be well fomented.

19th.—The patient has had no relief since this operation; on the contrary, he has been in great pain and distress, and it is evident that he is getting weaker day by day; he has passed but very few fragments, and these have caused great irritation and difficulty in urination: independent of this he suffers severely from the irritation of the skin of the scrotum and perineum, and an abscess has formed on the right groin, and has been opened. The pulse to-day is very feeble, upwards of 120; tongue is much furred; the patient has been slightly delirious; he is only able to take fluid nourishment, which consists of beef tea, brandy, and gin; he is also taking plenty of diluents; and a draught every six hours, containing, Infus. Lini, ʒiss.; Liq. Pt. Mxx.; Tr. Camph. ʒss.

23d.—This poor man has been suffering terribly ever since, in consequence of the great amount of irritation produced by the retention of the fragments of the calculus; at times the pain which he suffered was excessive, causing him to groan out aloud; he was evidently sinking under this protracted irritation; his pulse became very rapid and feeble, his countenance dull and heavy, and he took little nourishment, and that chiefly in the form of stimulants: he

lingered on in this manner, and died last night.

Post-mortem examination.—The bladder and front part of the pelvis, together with a portion of the urethra, were removed; in clearing the bladder from its connections on the left side, a considerable quantity of pus was seen to issue after a stroke of the knife, and on closer examination it was found to come from out of the left urter, which was distended nearly to the size of one of the fingers; its lining membrane was excessively inflamed, and here and there coated with pus; the pelvis of the left kidney was also found to be greatly dilated and inflamed. The right kidney was inflamed, and in addition there were two or three purulent deposits in its substance.

The bladder was considerably contracted, much thickened, and its mucous membrane in a state of inflammation; the viscus contained upwards of an ounce of urine freely mixed with pus. The fragments of the calculus were numerous; some of them of small size, whilst others were large; one piece was as big as a chestnut; they were coated with phosphatic deposit. The urethra was very much inflamed.

This case, which has turned out so unfortunately, tends to show the uncertainty which surrounds the operation of lithotritry, and the difficulties the surgeon labours under in his decision as to what case of stone is or is not fit for such a treatment to be pursued; for here was an instance in which there was every reason to expect a successful termination. There was no evidence of disease of the bladder or kidneys; there was no obstruction in the urethra, and the urinary passages altogether were not by any means sensitive to pain after the introduction of the sound. It is true that the calculus was of considerable size; but its size was not such as to prevent its being broken up, and Mr. Fergusson, as he stated at the time of the operation, was chiefly induced to try lithotritry in this case, although the stone was large, in consequence of his having just before most successfully broken up a calculus of the same calibre in the person of an elderly gentleman: only two sittings were required in this instance, but all the fragments, which, when collected, filled a two-ounce phial, were passed with scarcely any irritation, although some of them were large and became so impacted in the urethra that Mr. Fergusson found it necessary to remove them by the scoop. It was the success of this case, together with the great similarity between the one and the other, that induced Mr. Fergusson to try the same procedure in his hospital patient; and there was nothing to lead one to

the supposition that it would not turn out as favourably: the event, however, proves that it is impossible to estimate beforehand what will be the result after lithotomy, even in cases to which the operation seems to be well adapted, and when the greatest amount of care and skill has been used: it is this very uncertainty which has made some surgeons shy of performing it. We unfortunately in this country possess no extended statistics of lithotomy, and therefore it is impossible with accuracy to ascertain whether the mortality is greater after this proceeding, or after the apparently more formidable operation of lithotomy: there can be no doubt that death not unfrequently follows lithotomy,—in cases, too, when everything appears likely to do well; and, when death does ensue, it is generally preceded by far greater sufferings than when it takes place after lithotomy.

Stricture.

In our report of July 12, we related part of the history and progress of a case of impermeable stricture, which had been complicated with stone in front of the neck of the bladder, and with fistulous openings in the perineum and abdominal wall, through which openings most of the urine came away. We shall now continue the case from June 1, on which day, as stated in the last report, Mr. Fergusson had been able, after dividing the stricture from within, to introduce a No. 2 silver catheter into the bladder.

June 3d.—No. 4 was introduced into the bladder without difficulty.

5th.—No. 6 was passed, but it gave the patient some pain. He is still low and weak, although he is much better than he was; his appetite is not very good, and what he takes is chiefly fluid nourishment.

18th.—This poor man has been improving so much since the last report, that he has been able to go out and walk about the yard at the hospital. The wound which existed in the perineum is not yet healed up, but that in the abdominal wall is now almost entirely closed up, and does not allow urine to come away. Although the passage along the urethra is pretty well opened, the urine does not pass in a stream, but only dribbles away. With the object of keeping the back part of the canal well patent, Mr. Fergusson, at his visit to-day, passed the elastic bougie through the perineal opening into the bladder, and at the same time passed a No. 4 silver catheter down the urethra.

27th.—There has been some difficulty in still further dilating the urethra. Since the last report, Mr. Fergusson was scarcely able to pass a No. 5 catheter through the

stricture, which has evidently contracted somewhat since the internal incision was made: to-day, both No. 4 and No. 5 were passed without difficulty, but still there was considerable resistance in all other respects: the patient is much improved. The fistulous opening in the belly has entirely healed up for some days; the opening in the perineum is not yet quite closed; the general health of the patient is much improved, although he is still weakly, but so well as to be able to go out and take a trip down the river in a steam-boat.

July 5th.—As there has still been some difficulty in getting larger instruments through the stricture, Mr. Fergusson had the patient placed under the influence of chloroform, and by means of the *urethrotome* before mentioned, divided the stricture much more freely than he had done on the previous occasion, so that he was enabled to pass a No. 8 instrument, which was ordered to be kept in the bladder.

9th.—The patient suffered some slight uneasiness after this operation; but the symptoms subsided in a day or two; and as the instrument last introduced was found to be quite loose in the urethra, and producing no irritation, it was taken out and a No. 10 was introduced with the greatest ease, and then left. From this period everything went on satisfactorily; the instrument was kept in the urethra so that it should become fully dilated; the hardness which was some time ago so marked in front of the urethra gradually disappeared; and the fistulous opening in the perineum, although it did not quite close, nevertheless much diminished in size. Under these circumstances, the patient was discharged on the 22d, as he was anxious to breathe his native air, which in his weak state was considered to be the best thing for him to do.

ST. GEORGE'S HOSPITAL.

REPORTED BY DR. BARCLAY,
Medical Registrar.

Extra-uterine Fotation.

SUCH cases are by no means of very rare occurrence; and the feature of peculiar interest in the present instance is the age which the fetus had attained before fatal hemorrhage occurred, which seems to have been in great measure due to the occurrence of partial hemorrhage at an earlier period, when coagula were formed round the sac in such a manner as to arrest any further hemorrhage for a considerable period.

Hannah ———, *et. 29*, admitted into

St. George's Hospital, August 10th, 1850, under the care of Dr. Bence Jones: is very anemic-looking; the catamenia have not appeared since May; she has been married ten years; had one child nine years ago, and has not been pregnant since. Her present illness commenced in March last with an attack of pain in the abdomen and sickness, accompanied by rigors followed by hot flushings and perspirations; the bowels are generally confined, often as much as three or four days, and were so at that time. This pain recurred with severity about five weeks ago, and she has never been entirely free from it since, although paroxysms sometimes occur of greater severity than others. She stated that she had an illness of precisely similar nature two years before, in which her medical attendant informed her that an abscess had formed and discharged itself *per vaginam*. The attacks of pain now last generally some three or four hours, and are often accompanied by vomiting of greenish and yellow matters.

On admission, she was much blanched in appearance; had a countenance expressive of much anxiety. She complained of pain almost constant in the abdomen, and lay with her legs bent; her tongue was rather coated; pulse 108, not strong nor sharp; bowels costive; the whole abdomen was tender, but not extremely so; was not tympanitic or generally hard, but a distinct fulness and firmness were observed at its lower part on the right side; and a short distance to the right, and below the level of the umbilicus, a hard, roundish, firm tumor was easily discovered; but the tenderness on pressure over this was extreme. The bowels have acted this morning, but with pain and forcing. Eight leeches were ordered to be applied to the right side of the abdomen, and afterwards a hot fomentation. She was also ordered to have 2 grains of Calomel, and $\frac{1}{4}$ grain of Opium every six hours, and a saline the alternate six hours. A common injection to be administered to-morrow morning.

11th.—The bowels have acted scantily, with pain and forcing; the passage of the urine also gives pain; the tongue is cleaner; pulse 104; pain easier. The calomel to be repeated three times a-day; to go on with the draught and the fomentation, and to have a dose of castor oil, followed by common injection, to-morrow morning.

12th.—The bowels acted freely before the injection was administered, and she feels much easier now; pulse 100, rather weak; tongue cleaner, and moist; the motions are fluid and darkish. To repeat the calomel twice daily, and to continue the draught.

15th.—Has continued to go on well till this morning, when she had another severe

attack of pain, lasting three or four hours, leaving the abdomen more tender, and a feeling of pain shooting through to the back. She has the appearance of being more blanched since her admission. (She had slight epistaxis yesterday.) The tumor appears to be more superficial, and very tender; the left side of the abdomen pretty flaccid, and free from pain; no tympanitis. To have 3 grains of Grey Powder, and 1 grain of Opium every night; a linseed-meal poultice to the abdomen, and a morphia draught whenever the pain returns.

17th.—Has slept pretty well; a dose of 3 drachms of Castor Oil ordered yesterday has produced a motion full of small lumps, but with little pain or forcing; pulse 92; tongue tolerably clean; much less tenderness to-day. Nothing further observed of the tumor, except that there seemed to be a separate fulness at the hypogastrium, quite distinct from the tumor, near the umbilicus. She was now to take 3 grains of Calomel on alternate nights, and $\frac{1}{2}$ oz. of Castor Oil on alternate mornings, with a morphia draught always at bed-time.

19th.—The motions following the first dose were not lumpy, but dark and bilious-looking. After a tolerable night, she was this morning seized by a return of the pain in the abdomen: the fomentations, which were always found to have given her relief on previous occasions, were immediately had recourse to, and the morphia draught given. In about two hours after the seizure, when the apothecary was sent for, she was already cold and collapsed: stimulants were given without benefit, and she died with all the appearance of internal hæmorrhage.

Post-mortem examination 26 hours after death.—When the abdominal cavity was laid open, a large quantity of dark coagulated blood was found lying superficially to the intestines, besides a considerable amount of dark blood-stained serum which had gravitated to the lower part of the peritoneal sac. In the midst of these coagula, and a very short distance to the right of the mesian line, and rather superficially, was found a very perfect fœtus of about three months old; the umbilical cord was perfect, and led through masses of coagulated blood to the remains, which were still nearly entire, of a sac in which the amnion and the placenta could be made out very perfectly, as well as a very distinctly enlarged Fallopian tube, which formed, to a considerable extent, the investing membrane of the sac: to the outer side, layers of fibrinous, partially decolorized coagula, which were adherent to the surrounding intestines and the uterus, seemed to indicate a previous hæmorrhage which had been arrested; the uterus itself was very considerably enlarged, was of a

eastliſh texture, and was lined by a very well-marked deciduous membrane; the ovary of the right ſide contained a very diſtinct true corpus luteum; the other viſcera were all tolerably healthy, and were only remarkable as being very much blanched, which was moſt eſpecially the caſe with regard to the lungs, which were of a pale aſhy colour.

A queſtion of intereſt ariſes in all ſuch caſes, whether it be at any time poſſible to make a clear diagnoſis, and whether any operation might be reſorted to with a hope of ſaving the patient's life. In the foregoing inſtance ſuch a diagnoſis was ſcarcely poſſible. The circumſtance of the patient's having been nine years without giving birth to a child, rendered her pregnancy at that time highly problematical, while her anæmic ſtate was perfectly ſufficient to have accounted for the abſence of the catamenia. In addition to this, her own account is to be taken into conſideration, that her illneſs began in March, and that ſhe had continued to menſtrate till May, even ſuppoſing no account is taken of a former illneſs, of the particulars of which ſhe was probably miſinformed. Of theſe former illneſſes it is now difficult to form any idea, as no poſt-mortem traces of them were left; but it is very eaſy to conceive that the period of the recurrence of the ſymptoms which ſhe eſpecially marked as five weeks before her admission, very probably correſponded to the firſt hæmorrhage which had been arreſted; and it is highly probable that at that period the fœtus eſcaped into the abdominal cavity, where its growth continued, from the circumſtance of the placentas and cord remaining entire.

There can be no hope of ſaving the patient's life by any other means than an operation; and the development of the uterus, ſimultaneouſly with the growth of the fœtus, while it ſtill does not acquire the ſame ſize as the normal uterus which contains the fœtus within its walls, is perhaps almoſt the only means we have of aſcertaining the exact nature of the caſe, which muſt, under any circumſtances, be ſurrounded by difficulties, and the more ſo as they generally terminate fatally at a very early period.

APOTHECARIES' HALL.

NAMES of gentlemen who paſſed their examination in the ſcience and practice of medicine, and received certificates to practice, on Thursday, 5th September, 1850:—John Lee Jardine—John White Keyworth, Axton Tirrold, Berks—Walter Monday, Olveſten, Glouceſtershire—John Fourness Brice, Pontefract, Yorkſhire.

Medical Trials and Inquiries.

SUPREME JUDICIAL COURT, BOSTON.

March 19, 1850.

REPORT OF THE TRIAL OF DR. WEBSTER
FOR THE MURDER OF DR. PARKMAN.

*Before Chief Juſtice Shaw and Juſtices
Wilde, Dewey, and Metcalf.*

[Continued from page 436.]

DR. WOODBRIDGE STRONG, *ſworn*.—I have been in practice ſince 1820, in Boſton. While I was a ſtudent of medicine I accepted every opportunity I had to practice diſſection. I have ſince I came to Boſton diſſected many a body, and meant always to be thorough in my work. I have been at different inſtitutions alſo, and am more diſpoſed towards ſurgery than to anything elſe. I have been obliged ſometimes to burn ſome remains. Once I had a pirate given to me by the Maſter, when I was living in Cornhill. It was very warm weather. I wanted the bones, and deſired to get the fleſh deſtroyed. I had a common fire-place. The body was not a large one, but muſcular, and had ſome fat. I made a fire of wood and fleſh, and kept poking and keeping up a roaring fire. It burned all night, and up to three in the morning, and the maſs was not half burned up. Coal is bad to burn it with; but wood is good; though little fleſh can be burnt at a time. Any dry wood, ſuch as pitch pine, would do very well to burn. The ſmell is difficult to allay, and the operator would be apt to be found out through it.

[Witness deſcribed the remains as others had done.] The diſſection of the breſt was done in the uſual manner of anatiomiſts; and no one who had not been in the habit of ſeeing diſſections could have done the thing in the way it was. The muſcles between the bones were cut through as far as four inches,—the diſtance the fleſh was taken from off the ribs. The ſkin at the puncture was taken away; and ſome one ſaid, when I inquired about it being a ſtab, that it was not. I noted that the aperture ſeemed as if a ſtab had cauſed it when the muſcle was tight. It takes a very ſharp knife to make a clean cut, when the ſkin is not tight. I ſaw a perfectly clean cut made, ſo as nearly to graze the rib, which I thought muſt have been given when the body was alive. I thought it might have been the means of death. If a perſon was ſtabbed to the heart, ſomething would depend on the poſition of the wound

as to the hæmorrhage. In this case it would have been internal. In the case of these remains, the parts were peculiarly bloodless. They seemed as much so as meat that is seep in the examples. I observed the hair to be gray or whitish. The skin had lost the elasticity belonging to the young subject, and its thickness denoted age. I judged from the remains, from the hair, and the condition of the cartilages, that the person must have been between fifty and sixty. The body was unusual in its formation, from its narrowness across the shoulders, in proportion to the pelvis, and the tenuity in the upper part. It corresponded, in these respects, to the late Dr. Parkman's general appearance when alive. He had a peculiar appearance. There was nothing dissimilar to what I would have expected to have found in his remains; on the contrary, there were many points of resemblance.

Cross-examination.—I resided in Cambridge Street, No. 5, at the time. I went there in 1842, and have had acts of kindness from Dr. Parkman. We communicated together, and visited each other; and I have the pleasure of thinking he was one of my friends. The colour of the hair on the body was the same as that on his head and face. It is not so invariably. I don't recollect whether he had whiskers or no. If there had been any disproportion of the parts found, to indicate that they belonged to different bodies, I should have seen and noticed it. I am in the habit of looking at the human body regularly, and noting beauties or deformities. I did not see the remains the first day I called; but I saw them on the second day. I think I saw Dr. C. T. Jackson there, and I held some conversation with Dr. Lewis. I never burned up a body in a furnace. I think that the intensity of the heat would be as great in a stove as it would have been in the furnace I saw in Dr. Webster's laboratory. The stove I saw in the same room was a better article to use. I saw but one furnace in the College. I have used a common stove, when dissecting, to consume human flesh, with anthracite coal, which I think is not so good as wood. A large coal fire would burn up human flesh. It might be possible that the wound might have led to the heart, and no blood flowed outward. This could be accounted for by the form of the wound, which might collapse; and also by the sudden stopping the circulation of the blood, such as cutting the aorta would effect.

Direct examination.—There is a diversity of opinion among medical men regarding the weight or amount of blood in the human body. It might average forty pounds in a healthy man.

By a Jurymen.—I noticed the body perhaps more particularly, on account of its being supposed to be that of Dr. Parkman.

By Mr. Clifford.—Both the back and front of the body looked as if it might have been Dr. Parkman's.

Dr. FRANKLIN S. ALMSWORTH, sworn.—Am demonstrator of anatomy in the Medical College. All subjects must come through my hands. Keep a record of all anatomical materials. My attention was called to this record at the time of finding these remains; found I had all the subjects and materials I ought to have; all were accounted for. Examined the remains, and came to the conclusion, from the remains themselves, that they had never been sent to me or to the College for dissection. All subjects sent for dissection are injected with fluid, to preserve them from decomposition. I use a solution of arsenious acid, or chloride of zinc, with a saturated solution of alum and saltpetre. Dr. Webster has no connection with the anatomical department. My impression was, that the person who cut up these remains had no anatomical knowledge. The person who did it might have seen a body cut up, but I should doubt whether he ever took a knife in his hand to do it.

Dr. CHARLES T. JACKSON, sworn.—Have given attention to chemistry for several years. Went to the Medical College on Saturday, the 1st of December. Went with Dr. Gay. Dr. Lewis was there, and made some preliminary examinations. Dr. Gay and myself undertook the chemical part. There were shown us the remains of a human body. I took some observation of them; there was nothing to indicate that they had been used for the purpose of dissection. The body indicated some knowledge of anatomy on the part of the person that had divided it. There was no hacking about it; the thigh and hips were disarticulated neatly. I heard the testimony of Drs. Gay and Stone, and coincided with them. Was acquainted with the late Dr. George Parkman; he was very frequently at my office: he was a tall and slender man, and was otherwise peculiar. Did not see anything in the remains dissimilar from Dr. Parkman. There was nothing differing from what I should expect in Dr. Parkman, in the muscular developments of the lower parts. The flesh showed indications of chemical application.

[The report of Dr. Jackson was now read.]

I, Charles T. Jackson, being duly sworn, depose as follows:—I am, by profession, a physician and chemist. On the 1st day of December, 1849, I was requested by James H. Blake to accompany Dr. Martin Gay in

making some chemical and other examinations at the Massachusetts Medical College, in the city of Boston; and at four o'clock in the afternoon of that day I went with Dr. Gay to the Medical College, and there met Dr. Winslow Lewis, jun., and others, with the coroner of the county of Suffolk, and the jury of inquest. We made a general examination on that afternoon, and adjourned until Sunday morning, when we resumed our examination, Dr. Jeffries Wyman being associated with us, and aiding in the examination of the bones found in the furnace of the chemical laboratory; and also took chips of wood on which we had been shown certain brown stains, which were submitted to Dr. Wyman to examine. Dr. F. S. Ainsworth also assisted us in the selection of fragments of bone from the cinders of the furnace. The bones found by us were in a mass of cinders and ashes which had been removed from the furnace by the police officers, and were placed in a box, and had the appearance of having been exposed to fire. They were much broken, and were, in some instances, partially fused into the cinders. We identified at that time the following bones: right os calcis, right astragalus, tibia, and fibula, phalanges resembling those of the ring or middle finger; coronoid process of the lower jaw, and numerous fragments of a human skull; a human tooth with a hole in it, appearing as if it had once been filled by a dentist's operation; three blocks of mineral teeth, with platinum rivets in one of them entire, but wanting the gold plate on which mineral teeth are usually set. A pearl shirt-button was also found in the ashes of the furnace, and was partially calcined. Numerous little copper cups found in one of the laboratory drawers; they did not appear to have been burnt. Many pieces of glass were also found among the slags and cinders of the furnace. Masses of metal were also found, which proved by analysis to consist of, in 25 grains: tin, 12.19; lead, 11.95 = 24.14. Hence, it is evidently tea-chest lead. The cinders of the furnace, pounded and washed, yielded globules of gold, some silver, and a little copper. In the portion of slags and cinders worked by me, thirty grains of gold were found. My attention having been called to the state of parts of the human body which Dr. Lewis was examining, I took portions of the skin and muscles from the thorax, and tested them by reddened litmus paper, and found those parts strongly charged with alkali. I found the discoloured thigh also had been imbued with alkali, and stained by the fire. I took portions of skin from the arm and thigh, and carried them to the laboratory, and ascertained by chem-

that the alkali contained in them was potash, mixed with a very little sea-salt. The skin in several places appeared to have been corroded by the joint action of potash and heat. The thorax had singed hair on it, showing the action of fire, and probably of flame, since the burning was superficial. I found no alkali in the interior of the thighs, nor in the flesh beneath the skin of the thorax. The muscles of the cut surfaces at both ends of the thorax were strongly alkaline. I observed that the skin near an opening near the sixth and seventh ribs was quite tender, and the edges of the opening into the thorax were corroded, as if by potash. I dissected out the arteries and some of the veins of both thighs and of the leg, and gave them to Dr. Martin Gay. I subsequently saw Mr. Richard Crossley in my laboratory, in my presence, examine a portion of one of these vessels, with the adhering muscle, for arsenic and zinc, and saw that no trace of those substances was found. The spots on the walls, floor, and furniture showed us, were committed to Dr. Jeffries Wyman, who cut out chips from them in my presence. A pair of slippers was submitted to us by the officers, and Dr. Jeffries Wyman cut pieces off from them in my presence, and took them away with him. Dr. Martin Gay took portions of the cinders and metals for examination, and his results should be compared with mine, in order to ascertain how much gold was found among the cinders. CHARLES T. JACKSON.

Attest, J. L. ANDREWS.

I was instructed by the Attorney-General, on the occasion of the presentment of the Grand Jury, to take possession of those articles found at the Medical College, which were left with Dr. Gay. Went to his house and got them. Took them to Mr. Crossley. (Had made a previous examination of them with Dr. Gay, and turned them over to him for further examination.) Mr. Crossley is in my employment, and occupies a part of my laboratory. My test, as to whether there was alkali in the body, was satisfactory to me. The action of potash on the human body softens the flesh, and dissolves it after a while; and when heat is supplied, it dissolves it very rapidly. With suitable apparatus, the time taken to dissolve a human body with potash would depend upon circumstances; if it were cut up in pieces and boiled, the flesh would dissolve in two or three hours. For this, it takes of potash nearly half the

; and if the whole were very large kettle. To entirely (he weigh-), it would take of potash. Exa-

mined Dr. Webster's laboratory. The largest kettle that was there was a tin boiler, with a thick copper bottom, such as is used in boiling clothes. If the body was cut up in pieces, it would have been adequate to dissolve it; but it would not hold the whole body, or the thorax. The next best substance to potash for dissolving a body is nitric acid; but potash is the best. Nitric acid would require a double portion; it would take the whole weight of the body, of nitric acid, to dissolve it. The effect of it, when applied to a body, would depend entirely upon caloric: if gently heated, it would give off very little gas; and, if boiled, a very large quantity. The odour of nitric acid is very disagreeable, but it is not necessary that the gas should be confined for the safety of the operator; an open vessel would do. I saw nothing large enough to dissolve any considerable amount of matter at a time in the laboratory. There were in the laboratory several bottles containing one or two pounds each, or perhaps more, some of nitric and some of muriatic acid, nearly full, on the window near the staircase. Did not examine all the bottles, but think there was not more than ten pounds of it altogether. There was on the wall (which was painted white), and on the staircase side of it, drops of green liquid. (The stairs were those leading from the back room in the rear of the lecture room.) I sent to my laboratory and got some filtering paper, which would absorb the green liquid. Dr. Gay took that paper and absorbed some of it, and carried it home with him. Since I received the things that Dr. Gay had, I have examined that paper, which I recognised to be the same paper with the green fluid in it, and found that green fluid to be nitrate of copper. The drops were very abundant in quantity, extending all along the stairs, from top to bottom, and on the adjoining wall. Was satisfied that it was nitrate of copper; think it was spilt on the stairs, and did not run down from the top. The drops were more abundant at the bottom than at the top of the stairs. Nitrate of copper attracts moisture from the air, and remains in a liquid state a long time; the stains were in a fluid state when I was there. Nitrate of copper has an astringent acid taste, like copper. With regard to the spots of blood, I was requested by the Government to make an examination of them; but considering the blood a more proper subject for microscopic observation, I transferred the duty to Dr. Wyman. Have had no experience of the effect of nitrate of copper on blood. A pair of pantaloons was discovered, with spots of blood on them. I think it was on Sunday Dr. Wyman cut out pieces from them. A power-

ful microscope is the only test to discover small spots of blood. Slippers were also found with appearances of blood on them. Dr. Wyman cut pieces from them also. Several punch pieces of copper were found in one of the drawers in Dr. Webster's laboratory. Others were found, much thinner, under the furnace, having upon them nitrate of copper,—showing that the oxide of copper had probably been introduced into nitric acid, for the purpose of making nitrate of copper.

	Grs. Gold-
I found in that given to me . . .	45 $\frac{1}{8}$
Dr. Gay found	47
And in a piece brought to me by Mr. John L. Andrews, the se- cretary of the coroner's inquest, I found	81 $\frac{1}{8}$
Total	173 $\frac{1}{8}$

The market value of this gold would be 6 dollars 94 cents. There is some gold still remaining in the blocks of teeth. Think I did not extract all the gold from the furnace; there might have been some left.

Mr. Bemis.—Is there any change in the appearance of the bone by being in fire in connection with gold, giving any indication of the proximity of the gold to the teeth?

Dr. Jackson [examining the bone].—It is the same colour that we see in the slag where the globules of gold are found—a pink colour produced by oxide of gold. It is on a block of artificial teeth. The contents of the ash-pit were taken out,—a part of them while I was there, the remainder not. The bones indicated that intense heat had been applied. Anthracite coal had been used at a high temperature. I have known the defendant for twenty-five years; have studied with him, and been on terms of communication with him. I have noticed the knife [exhibiting the sheath-knife] in Dr. Webster's laboratory, when I studied in the old Medical College. The College was removed to Grove Street in 1846. We found whiting and fresh oil upon the knife, as if there had been an attempt to clean it. This was on Monday or Tuesday. One of the officers called my attention to it. I scraped it off, carried it home, and analysed it. The whiting was not dry, but moist, and soft as putty. I did not notice the handle. Dr. Parkman was about my height, which was five feet and eleven inches.

Cross-examination.—The back, one side, and the two ends of the remains, were covered with potash, but no other part of the thorax. The thigh-bone was smoked, and the skin was softened, as if by potash and heat. If the bones had been separated

from the flesh. I think they could have been dissolved in half a day. There was nothing at all in the large boiler I mentioned before, when I saw it. I suppose the whiting had been used in cleaning the knife-handle. Tried the effects of nitrate of copper on wood, and it produced the same stains that we saw on the stair-case. [Here a piece of wood, with the above stains on it, was shown to the Court.]

RICHARD CROSSLEY, *sworn*.—Have given attention to chemistry for thirteen years. Have examined the blood-vessels, at the request of Dr. Gay, to ascertain whether they were, as usual, injected with arsenic acid and chloride of zinc, and found neither of these substances present. These are the injecting substances used at the Medical College. I coincide with Dr. Jackson in his opinion about the nitrate of copper.

DR. NATHAN C. KEEF, *sworn*.—Have been in the practice of dentistry for thirty years. Give attention both to natural and artificial teeth. Knew Dr. George Parkman as early as 1823. When I was a student to Dr. John Randal, Dr. Parkman was frequently there; and on one occasion was quite sick, and Dr. Randal attended him. When he recovered he was at Dr. Randal's very frequently, and I was acquainted with him at that time. As early, I think, as 1826, he employed me as his family dentist; and since that time, whenever he needed assistance, I have been the person on whom he called. Was shown the block of mineral teeth by Dr. Lewis. This was on my arrival from Springfield in the cars, the Monday after Thanksgiving, about one or two o'clock. I recognised them as the teeth I had made for Dr. Parkman in 1846. Dr. Parkman's mouth was a very peculiar mouth in many respects; differing in the relation that existed between the upper and lower jaw so peculiarly, that the impression left upon my mind was very distinct. I remember the peculiarity of the lower jaw with great exactness. The circumstances connected with the teeth being ordered were somewhat peculiar. The first question asked by Dr. Parkman, when the teeth were ordered, was, "How long will it take to make them?" I took the liberty to ask why he was so particular to know. He told me that the Medical College was to be opened, and that it was necessary for him to be there, and perhaps to speak; and he wanted them by that time, or else he did not want them at all. That time was a very short one. The peculiarity of the mouth made it a case requiring as much skill as could be used. I began to do it as soon as possible; gave a large part of my attention to it from day to day. In consequence of these circumstances, and the

shortness of the time, and the close application I gave to it, I remember very distinctly what was done, more than in ordinary cases. I proceeded in my usual mode to take the impression. The first step was, to take an exact *facies* of each jaw with wax, metal, liquid plaster, &c. A plate was made from that; and the next step was, of course, to ascertain the relation between the upper and the lower jaw. A model of the lower jaw was made from an impression taken with wax, while in a plastic state; and by means of this the lower plate was fitted. The upper plate was fitted in the same manner. [Dr. Keef exhibited the original plates, which fitted to the models.] These plates were made before the gold plates, to ascertain if there were any defect in the models. When the plates were fitted to his mouth, I requested him to close it until I satisfied myself as to the suitable distance. A great irregularity on the left side of the lower jaw of Dr. Parkman gave me great trouble in getting this up. Each set of teeth was made in three blocks, and then joined to the gold plate. There were spiral springs that connected the two sets of teeth, to enable the patient to open his mouth and close it with less danger of the teeth being displaced, as they would have been without the springs. There was an accident which injured one of the teeth in the front block, and delayed the finishing of them until near the end of the night before the opening of the Medical College. My assistant was Dr. Noble. When I next saw Dr. Parkman, he said that he did not feel that he had room for his tongue. In order to obviate that difficulty, I ground the block of the lower jaw on the inside, to make it lighter, and furnish more room for the tongue. This grinding, at that time, was not accomplished with so much ease. The teeth being on the plate, we could not grind on a large wheel. We had to grind on a very small wheel. This grinding removed the pink colour that represented the gums, and also the enamel from the inside of the lower teeth. The beauty of it was defaced by this grinding. The shape left by the grinding was very peculiar, because of its being ground on a small wheel, smaller than itself. I saw Dr. Parkman frequently. The last time I saw him was, as near as I can remember, about two weeks previous to his disappearance. He called late in the evening, about ten o'clock. It so happened that, not being very well, I had retired for the night. The person who went to the door, seeing Dr. Parkman, asked him in, and went up and told me that it was he. I sent word to him that I would come down as soon as I could. He told me his trouble. I took his teeth, both upper and

lower, examined them, and put on a new spring. He staid about half an hour; when he was ready to go home. I had no more professional intercourse with him at all. I went into the country to pass Thanksgiving at Longmeadow, and returned on the Monday morning after Thanksgiving. Arrived home, I was told that Dr. Lewis wanted to see me; and he presented me with these remains of mineral teeth [showing them], with the request that I would examine them. On looking at them I recognised them to be the same teeth I had made for Dr. Parkman. The most of the upper portion that remained was the block belonging to the left side of the lower jaw. Several other parts had been very much injured by fire. I proceeded to look for the mould upon which these teeth were made, put the metal upon its proper place, and it fitted exactly. There is sufficient left of these blocks to identify the place where they belonged. There is no mistake. [He then showed the mould and remains of teeth, &c.] All the pieces having been found, there were five pieces, which fitted to their exact places. The only piece that could not be identified might or might not have been right; but it was supposed to be right, as there was no reason that it should not be so. [The blocks of teeth, &c. were here shown to the jury by the witness, and afterwards to the Judges. During the progress of Dr. Keep's testimony, the Court and the witnesses were affected even to tears, and Dr. Keep, particularly, was overcome with emotion.] I found imbedded, more or less, with these mineral teeth, some very minute portions of gold, which is termed cancelled, being peculiar to the jaw-bone. I saw the teeth in the doctor's head the last time I saw him, in conversing with him. The presumption is very strong that these teeth were put in the fire in the head. Such is the nature of these mineral teeth, that, especially if they have been worn, they absorb small particles of water; when suddenly heated, the surface becomes closed, and the water becomes steam, and there would be a report, with an explosion. I have known such explosions to take place on heating teeth that have been worn; and when they have been worn recently, the explosion is always sure to take place if heated rapidly. If, while in the head, they were put into the fire, only a small portion would be exposed to the heat; and as the temperature would be raised so gradually, the water would have time to escape; and this accounts, in my mind, for the teeth not being cracked, excepting the front teeth, which would have been most exposed. I have found fused into the remains of teeth portions of the natural jaw. All these

teeth were exhibited to me at the same time.

Cross-examination.—My first impression, on seeing the teeth shown me by Dr. Lewis, was of the circumstances which I have related. Do not think I have been burlesquing up my recollection since they were shown me. Knew them for myself, without examining the mould; but I did examine them with the mould. The mould of Dr. Parkman was preserved, as moulds usually are, for future use in case of accident to the teeth. I heard of Dr. Parkman being missing before I went into the country. First time I heard of his being missing was the first night it was advertised in the papers.

Dr. LESTER NOBLE, sworn.—I was an assistant of Dr. Keep, in 1846, and remained in his service until 1849. Am now pursuing my studies in Baltimore; am a student at the Baltimore College. Recollect working upon teeth for Dr. Parkman; it was in the autumn of 1846. [Here he was shown the mould of Dr. Parkman's teeth, and recognised his handwriting on it.] Yes, this is my handwriting.—“Dr. Parkman, in October, 1846.” I did recognise these teeth. Was called to the Attorney-General's room; the blocks were brought in under seal, and there I examined them. They were delivered to me for safe keeping; and I have kept them in my pocket since, until they were called for to-day. The circumstances accompanying my recognition of them were, in the first place, the general shade of the block, which was the same that I remember to have worked upon for Dr. Parkman. Also I found on the inside a surface which appeared to be ground. At the moment I saw it, I recollected that this block of Dr. Parkman's teeth had been ground in the same way; that I saw Dr. Keep grind them. It was after the doctor had worn them, after he had been to the Medical College with them, that he said his tongue was incommoded. I have every reason to believe that the blocks were Dr. Parkman's teeth, and no reason to believe that they were not; have as good reason to believe it as any other fact. I have not the slightest doubt that they were the blocks I worked upon for Dr. Parkman. We were obliged to be very prompt in making the teeth to the time of an appointment by Dr. Parkman. They had to be ready at the time, because Dr. Parkman was sure to be there at the very moment he appointed. The time of the appointment of their being finished was when he wished to attend a meeting at the Medical College. An accident which occurred in blocking spoiled a part of the front block; it occasioned the necessity of remaking it, which of course caused delay, so that we had to work upon

hem a large portion of the night; remember that I worked upon them almost all night. We got them finished just in time for Dr. Parkman to go over to the College with them. I want myself, in order that I might see, when the doctor had occasion to peak, how well he used them. Think it was in the early part of November that the Medical College was opened. I rather think he did not speak; merely, when complimented for his generosity by Governor Everitt, he acknowledged it with a bow; yet I am not confident but what he said a few words. I understood that he had been liberal in a donation, by furnishing the ground, &c. The Medical College was opened in the early part of November. It was in the early part of my studies that I worked on Dr. Parkman's teeth; I began about the 11th of September. We first make the impression in wax. I made the moulds of these teeth in the wood, and made the metal casts. Could not tell precisely how much time was spent on them: it must have been quite a number of days. Have put blocks of teeth into the fire, to see how easily they would crack, and I have never known them not to crack; they may be heated up gradually and cooled with perfect safety. Coincided with Dr. Keep as to his opinion. Some time after the fitting of the teeth—about a year, I think—an accident happened to them; they bent together, and they had to be re-annealed to the pattern. I had to heat them for this purpose, and the mark of the blow-pipe still remains.

[To be continued.]

Correspondence.

INFLAMMATION AND ABSCESS OF THE UTERINE APPENDAGES.

SIR,—Since the publication in your valuable weekly journal of my paper on "Inflammation and Abscess of the Uterine Appendages," my attention has been directed to some very interesting cases which appeared in the Transactions of the Provincial Medical and Surgical Association for 1841, contributed by Mr. Wainwright, of Liverpool. Although, in the remarks accompanying them, the writer considered any observations he could make "must necessarily be of a speculative character," yet, as he apprehended that such "cases have usually been regarded as examples of either pueral abscess, or some other disease of this region already brought under the notice of the profession," and published them merely "in the hope that some attention may be

attracted to the subject," I think that, although he failed in developing the subject, and that Deherty in 1842, Churchill in 1843, and others subsequently, have been more successful; yet he having, of British writers, been, as I believe, the first to call professional attention thereto, is in my opinion deserving of honourable notice; and I accordingly regret I did not see that volume of the Transactions before.

I am

Your obedient servant,

M. JENNETTE,

Surgeon to the Birkenhead Hospital.

Sept. 9, 1850.

Medical Intelligence.

EPIDEMIOLOGICAL SOCIETY.

Dr. Babington's Speech, made when he proposed the Establishment of the Epidemiological Society at the General Meeting held at the Hanover Square Rooms on the 30th of July, 1850.

I FEEL that I should best consult the interest of the Society which we have met to form this evening, if, after the excellent, the admirable speech which has just been delivered by his lordship, I were simply to read the motion placed in my hands, and say nothing; but I have undertaken a task, and, in justice to myself, I must go through with it.

Gentlemen—Before I proceed further I wish to make one observation. It has been said and believed by some that I am the founder of this Society. Certain expressions in some of the medical journals have given rise to this impression. I wish to set myself right with the public on this head. I have no claim to be considered as the founder of this body: that merit belongs to our worthy Secretary, Mr. Tucker.

In common with others, when he called upon me I responded to his call, and was anxious to aid, as much as in me lay, to forward the views of such a valuable institution. I think no better time than the present could have been chosen for the formation of this Society. With the exception of some few sporadic cases, we are at present free from cholera, or any other epidemic—free from that fearful proximity which is so apt to disturb our powers of reflection.

Physical science, too, has made remarkable progress within the last half century; so that we can approach the investigation of epidemic diseases, as it were, under new circumstances. Animal chemistry is a new science. Fifty years ago it was almost un-

known. Meteorology, too, is quite a new science. The microscope, also, has done wonders; and such are the improvements in its construction, that its powers may be said to have only lately been developed: while physiology, human and comparative, has made most astonishing progress. This, then, is the time for the establishment of such a Society as ours; for, with these new instruments to aid our researches, we can hardly fail to add to our knowledge.

Gentlemen—It has been said, and by clever men too, that great discoveries are not to be made by bodies of even the most scientific men; that they do not result from the combined efforts of many, but that they rather spring from the genius of single labourers, who feel themselves called by the force of enthusiasm to the work, or by their peculiar circumstances are led to concentrate some thoughts upon particular subjects; that the formation, therefore, of a Society such as this is superfluous, seeing that individuals will of themselves come forth and elucidate those matters for the investigation of which it is formed.

This is partially true, but not wholly so. There are investigations which it requires the combined efforts of many to make on a sufficiently grand scale to be useful. Besides, we do not purpose to interfere with individual exertions, but rather to aid them, by placing materials at their disposal, such as books and instruments,—by publishing their productions, and by making them acquainted with the scientific researches of men of other countries.

Granting that individuals for the most part *make* discoveries, societies *arrange* them, and render them practically useful. The advantages of combination are almost too well known to need illustration. Take, for example, the variation of the compass, a knowledge of which is so essential to safe navigation. How could it have been determined but by the combined observations of many simultaneously made? Take, again, the theory of storms: Col. Reed could never have demonstrated the truth of this had it not been for the information and assistance afforded by numerous observers stationed in all parts of a great circle on the ocean, and simultaneously recording physical facts.

Gentlemen—We have a large subject before us in the investigation of the causes of epidemics, and especially difficult is that branch of it which relates to contagion. If we pronounce an opinion in favour of the doctrine of non-contagion, and that opinion be correct, we are enabled at once to take off the fetters of commerce imposed by quarantine, and thus to grant a great boon to mankind; but if that opinion be erroneous, how fearful is our responsibility in

so doing! We admit the seeds of death into the heart of populous cities, and the most awful results—the destruction of myriads of human beings—may follow.

This, then, is a momentous question, and one about which there is a vast difference of opinion among medical men; and it will be for us, aided by the new light of science, to elicit the truth from the conflicting testimony submitted to our judgment. One gentleman to whom I wrote, requesting him to join our Society, felt so strongly on this very question that he declined doing so,—on the sole ground that it would engross all our attention, yet without any hope that it would after all be settled. We must, therefore, be cautious, being thus warned, not to suffer it to claim more than its due share of our labours.

There is another almost equally important question,—that of the incubation of diseases,—of how long, for instance, scarlet fever remains in the affected before it makes its outward appearance: again, as connected with this subject, how long a habitation where such disease has prevailed remains capable of imparting it to newcomers. Were I called upon to answer such a question in the case of scarlet fever, I really could not speak with anything like certainty. Others may no doubt have much more experience than myself in this matter; but I candidly own that I could not determine the point, even within the wide limits of a month or two.

Then, with regard to the treatment of epidemic diseases, we have a wide field open to us. If we instance cholera, we know that a vast amount of thought has been expended upon the subject; but still we have no leading principle,—no guiding circumstances,—no collection of facts sufficiently ascertained to enable us to come to any safe and certain conclusion.

It by no means follows, however, that we never shall do so. There was a time when it was a question quite unsettled whether bleeding in yellow fever was beneficial or otherwise. It is now determined, from the testimony borne by a vast collection of facts, that bleeding is fatal in that disease. There is not a recent book that you can take up on the subject in which you do not find it condemned. And how was this question set at rest?—Why, by individual medical men carefully marking the results of bleeding in numerous cases, and comparing their observations. Had we but a single fact in the treatment of cholera as certain as this, it would be interesting and valuable; but we cannot affirm that even this is the case.

The learned Doctor then dwelt upon the necessity of the Society having ample funds at its disposal, in order to enable it to make

inquiries in all parts of the world, to organise scientific investigations in different departments and in various parts of the globe, and to give publicity to the results of its manifold labours.

One good at least (continued the Doctor) must arise from our exertions under any circumstances—namely, that the public will feel that the medical profession are not apathetic, but actively employed in using their best exertions for the benefit of their fellow men.

I may mention, before I sit down, that it is proposed to fix the annual subscription at one guinea. Of course it is not intended to limit members to that sum. If the laity who may not be able to assist in any other way feel inclined to increase that amount to any extent which their means, and the great objects to be accomplished, may warrant, we shall feel most grateful for such aid.

The Doctor concluded by moving the first resolution.

UNIVERSITY OF ST. ANDREWS—MEDICAL
EXAMINATION PAPERS, AUGUST 1860.

First Examination.

1. Explain shortly the nature of chemical affinity, and give two or more examples.
2. In what manner is phosphorus usually obtained, and what compounds does it form with oxygen?
3. Explain the nature of the change effected upon sugar during the vinous fermentation.
4. Give one of the usual processes for the preparation of iodide of potassium.
5. Classify the most important mineral waters according to their composition, giving one or two examples of each variety. Describe briefly their actions and uses.
6. Mention the effects, uses, and mode of administration of elaterium, strychnia, monkshood, aconite [aconita, *Ph. Ed.*], gallic acid, nitrate of silver, the iodides of mercury, and the arsenious solution of the British Pharmacopoeias.
7. What is copaiva? Describe its actions and uses. Write (without using abbreviations) a Latin prescription suitable for an ordinary case of gonorrhoea, and containing copaiva and spirit of nitrous ether.

To be translated into English.

Sonorum immensa varietas est; quippe quorum vel levissimae mutationes et conjunctiones ab acuta et docta aere percipiuntur. Insignis quoque eorum vis est in animum hominis, et ideo in corpus. Variae animi affectus, tristes insuperis et laetæ, inspirant; neque hominum ex hoc inexhausto fonte puræ et suavissimæ velup-

tates hauriunt. Auris vero, quæ vocatur musica, non omnibus datur; cujus rei ratio hæcenus latet. Nullo modo pendet ab acutiore vel obtusiore auditu. Semisurdi nonnunquam musicæ sâtis periti sunt et amantissimi, quæ bene audientes parum sæpe frutuntur: et vir, auditu integro manente, aurem suam musicam, quam eximiam habebat, subito et sine nota causa amisit. Neque ratio ulla est cur defectum talem inæquali per bimbas aures auditui imputemus. Facultas ipsa Naturæ donum est, nullo studio acquirenda: cultu vero et usu, non secus ac reliquæ hominis facultates, mirum in modum acuitur et roboratur. Auditus fere omnium sensuum sæpius vitatur: quod profecto nil mirum; scilicet, quia organum habet delicatissimum, et ex plurimis et valde minutis partibus compositum.

Second Examination.

1. Give a classification of the different kinds of food, stating the uses of each class in the animal economy. What do you consider to be the quantity of solid food necessary for a healthy adult? Give the symptoms, and appearances after death, in cases of starvation.
2. Describe the course of the left subclavian artery, mentioning its most important connections, and the branches which it gives off.
3. Describe briefly the anatomy of the pneumogastric nerve, pointing out the difference of its course on the right and left side. Mention the most important functions of this nerve, and name some of the diseases or morbid conditions of the system in which you suppose it to be involved.
4. Describe the duodenum, the nature of the secretions which are poured into it, and their influence in the process of digestion.
5. Give a sketch of the physical and chemical characters of healthy urine, mentioning the average amount of urea and uric acid excreted in twenty-four hours. What effect is produced on the urine by the administration of benzoic acid?
6. Mention the peculiarities of the fetal circulation. State what you conceive to be the principal office of the placenta. Describe the nature and causes of the sounds which are heard on auscultating the uterine region during pregnancy.

Third Examination.

1. Describe the different modes of death, mentioning their symptoms and some of the diseases in which they respectively occur. What are the most frequent causes of sudden death?
2. Give a description of the paroxysm in hysteria, and contrast it with that in

epilepsy. Mention the diseases most commonly simulated by hysteria, and show how the true nature of these cases may be detected. Give a sketch of the general principles of treatment, both during the hysterical paroxysm and in the interval.

3. Describe the organic causes and the treatment of pulmonary hæmorrhage.

4. Describe the causes, symptoms, and treatment of abscess of the liver; and mention some of the courses which the pus may take.

5. Give a sketch of the causes, symptoms, and treatment of erysipelas of the face and head. Mention the different ways in which it may prove fatal.

6. What are the causes, symptoms, and treatment of stricture of the rectum?

7. Mention briefly the symptoms and treatment of secondary syphilis.

8. Describe the symptoms of abortion, and the treatment of them.

QUEEN'S COLLEGE, BIRMINGHAM.

At the recent annual meeting of the Governors of this College, the following report was read on the medical department:—

"The Council have the satisfaction of witnessing, from year to year, the entrance upon life of the students who have received their education in this department of the College; and they are now able thankfully to point to many in extensive and lucrative practice, and holding public appointments, who were formerly students in this department. During the present year, Mr. P. H. Bird, who quitted the College in the year 1847, has obtained the Jacksonian Prize, awarded by the College of Surgeons, and open to all its members, for his Essay on the Nature and Treatment of Erysipelas. The Council hope that this success augurs for that gentleman a distinguished professional course. The Gold Medals on Dr. Warneford's foundations were adjudged, in October last, to—Stead and—Mills, for their Essays on the Brain. On the same occasion gentlemen received medals and prizes in the classes—*Materia Medica*, *Botany*, *Chemistry*, *Medicine*, *Midwifery*, *Surgery*, *Anatomy*, *Forensic Medicine*, &c. &c.

"The number of resident students in the College in Paradise Street has been greater during the present than any former year. The number of out-students is also satisfactory.

"The professors and tutors have delivered to the Council satisfactory reports of the conduct and progress of the students in their several classes. The Theological Lecture, endowed by Dr. Warneford, has been delivered during the present year by the warden, who reports favourably of the attendance and improvement of the students."

THE CHOLERA ON THE CONTINENT.

The cholera is still prevalent in various parts of Germany, especially in the Austrian empire. At Lubeck, from the 17th of July to the 24th of August, there were 918 cases and 451 deaths. In 1832, the deaths from cholera in this city were 800; and in 1848, from the 18th of September to the 30th of November, there were 575 cases and 301 deaths. At Malmo, in Sweden, the disease is also very prevalent. There were more than 300 cases in less than a month; and about one-fourth proved fatal.

Accounts of the 13th of August from Mexico mention the disappearance of cholera after 100 days' duration, and 18,000 deaths in that city alone.

PROFESSOR WEBSTER.

PROFESSOR WEBSTER was executed at Boston, on the 30th August, for the murder of Dr. Parkman.

DINNER GIVEN IN DUBLIN TO SIR BENJAMIN BRODIE.

THIS eminent surgeon was, on August 29th, entertained at dinner by the President and Council of the Royal College of Surgeons. In proposing the toast of the Royal College of Surgeons of England, coupled with the name of its most distinguished member then present, the President observed that he might upon such an occasion correctly allude to the great names which adorned its lists, and the benefits conferred upon the profession and the public by their exertions. He would not, however, do more than express, through Sir Benjamin Brodie, the feelings of gratitude which were entertained by the Irish College of Surgeons for the never-failing hospitality and kindness shown to its members by their brethren of the College of Surgeons of England, and the great gratification they felt in being able in the present instance to mark that feeling by paying a tribute of respect to the most distinguished living member of that body. It was difficult—very difficult, he said, to express in proper terms sentiments of admiration for a man who was good as well as great, when that man was present; but he felt that he was guilty of no flattery when he stated that he hailed their honoured guest as the first surgeon in the metropolis of the world.

SIR BENJAMIN BRODIE returned thanks for the honour done to himself and the College of Surgeons of England, and in doing so begged to assure those present of the high opinion entertained by English surgeons for the professional exertions and merits of the members of the Irish College, and of their endeavours to elevate their science from the position of a trade into that of a noble profession. He had

for more than forty years been acquainted with many of its members, and he could safely say that no body of men (in his judgment) more truly answered the characters of a scientific and gentlemanly profession than the members of the Irish College. It was not then the time to speak of the many improvements in surgery made by gentlemen of its body; but he could not refrain from referring to one of the latest—viz., the introduction of a bloodless mode of cure for the formidable disease of aneurism. The proofs he had witnessed of its efficacy during his stay in Dublin convinced him that it must soon supersede every other plan of cure. Such triumphs as these had secured the pre-eminence for the school of surgery in Ireland, and he trusted that it might long enjoy the honour.

Sir PHILIP CRAMPTON rose, and observed that, allusion having been made by their eminent guest to the treatment of aneurism by compression, he begged, in the name of the Council, to present to Sir Benjamin Brodie a trifling gift, but one that he might be gratified to receive—viz., a set of the instruments used in the treatment of the disease, fitted with the elastic spring, the valuable improvement of Dr. Carte; and to these he begged to add, from the author, the work of Dr. Bellingham on the subject.

OBITUARY.

DR. BENJAMIN WILLIAMSON, ABERDEEN.

WE have this week to record the death of Dr. Williamson, of Aberdeen. The deceased, who had reached his 62d year, was born on the 25th of January, 1789. In 1804, he became an articled pupil of the late Dr. French, then one of the medical attendants in the Aberdeen Infirmary, and Professor of Chemistry in the University. In the autumn of 1808 he proceeded to London, where he attended the surgical practice at Guy's and St. Thomas's Hospitals. Subsequently to this he became assistant to a surgeon in Cheltenham, returning to London, in November 1811, to enter the different classes then taught by Mr. Cline, Mr. Cooper, afterwards Sir Astley, Sir Benjamin, then Mr. Brodie, and Dr. Haighton. Early in 1812 he presented himself for the usual examination at the Royal College of Surgeons, with the view of entering the naval service as assistant-surgeon. Ultimately, however, he determined on returning to his native place, which he did about the close of 1812, after spending a few months at the Medical School in Edinburgh.

In Aberdeen, Mr. Williamson's first

charge was that of a public dispensary. In 1814 he became one of the medical attendants at the Royal Infirmary, the important duties of which office he continued to discharge, with much credit to himself and benefit to the institution; for the long period of nearly a quarter of a century. During his incumbency the present division of the duties of the medical officers of the Infirmary had not been effected; and, consequently, Mr. Williamson had to act there in the capacities both of surgeon and physician. Rare as such a double qualification is usually found to be, it would be difficult to say in which of these two spheres of action the services of the deceased were the more appreciated by the managers and the public. While he did much to sustain the previously well-earned medical fame of the institution, to him the merit is justly due of having been the first to originate the improved surgical practice which has since placed it on a level in this respect with the most efficient metropolitan establishments. In 1838 he resigned his situation at the Infirmary, and about the same time withdrew altogether from the operative department of surgery, in order to devote his time entirely to his extensive private practice, and to his numerous engagements as a consulting physician. His withdrawal from the Infirmary was deemed a fitting occasion on which to confer on him an honorary degree in medicine, which was done by Marischal College soon after. In general and in consulting practice, Dr. Williamson's career was most active and laborious till about two years ago, when, his health giving way, he almost wholly retired into private life.

We have already alluded to the rare union in Dr. Williamson of the best qualities both of the surgeon and the physician. For the former branch of his profession he was admirably qualified. As an operative surgeon, he had few equals amongst his contemporaries here or elsewhere. As a physician, however, it is that he will, perhaps, be longest remembered. His quiet and gentlemanly manners, his highly prepossessing appearance, and his undeviating cheerfulness, coming strikingly in aid of his ready resources, his never-failing tact and precision, and his long and varied experience, generally sufficed to secure for him the entire confidence of his patients, most of whom became in time his most attached friends. By his medical brethren Dr. Williamson had been placed, for several years before his death, at the head of the profession in that part of Scotland—a position considered by them as due to him, both from his sterling uprightness of conduct and his high medical requirements.

Selections from Journals.

ON THE POST-MORTEM APPEARANCES IN DEATH BY DROWNING. BY DR. RIEDEL.

The following are the results of a series of experiments by Dr. Riedell:—

1. The cadaveric rigidity does not occur more slowly than in other modes of death. This phenomenon is accelerated by high temperature of the water.

2. The accumulation of blood within the cranium was inconsiderable, and effusion of blood had not occurred in any case.

3. The epiglottis was constantly found erect.

4. The diaphragm was always found relaxed, its convexity being towards the thorax. The intestines were not pressed against the abdominal walls. The lungs were usually found in the condition of an imperfect expiration,—owing, doubtless, to the distension of these organs by fluid, the presence of which presented an obstacle to the collapse of the thoracic parietes.

5. In half the number of instances the two sides of the heart contained equal quantities of blood; in the other half the right side contained the larger proportion. In one case only the emptiness of the left side contrasted strongly with the fulness of the right. The quantity of blood in the liver varied greatly.

6. The bladder was sometimes empty, and sometimes full. It was almost always distended with fluid in animals drowned in a state of stupor.

7. The blood in the heart and large vessels contained coagula, in autopsies made from two hours to five days after death. Coagula were found three-quarters of an hour after death, in the heart of a cat drowned in boiling water (!), while in animals drowned in ice-cold water the blood was still fluid and cadaveric rigidity was absent.

8. In the majority of cases the fluid had passed into the stomach. In animals previously killed, and placed for twenty-four hours in water with the mouth wide open, no fluid penetrated to the stomach.

9. In every case the trachea, bronchi, and lungs contained a frothy fluid. This was a constant sign of death by submersion. After death, this frothy fluid gradually disappeared from the air-tubes by exosmosis, but not from the lungs. The fluidity of this froth is diagnostic of death by drowning, and is not met with in any other mode of death. Another equally important character was observed in the constantly flabby condition of the lungs, which are dilated and preserve the impression of the

finger on their surfaces. The lungs are also three or four times as heavy as natural. This diagnosis, however, is open to the objection that the same phenomena may be produced by the forcible injection of fluid into the lungs.—*L'Union Médicale*.

X

THE SIGNS OF DEATH.—DR. DOWLER'S THERMOMETRICAL TEST.

DR. DOWLER, of New Orleans, proposes the thermometer as a means of testing death, possessing as it does superior certainty over the stethoscope. The latter method takes for granted that in apparent death the heart's action still continues,—that it cannot be for a time suspended, and that it can always be heard! The very analogies of apparent or temporary death seem to oppose or contradict these assumptions. The analogies and the positive facts known of animal temperature teach that during life the body is not heated and cooled like inert matter. Place two or three thermometers in the arm-pits,—in the bend of the arm (the forearm being flexed),—in the mouth and within the sphincters, to ascertain the heat of the surface and of the centres (the rectum is the best and most accessible centre). The application of the thermometer requires no skill, and is open to the inspection of all; and is a test for all the warm-blooded animals,—at least for man. While the auscultatory test takes for granted that there can be no temporary inaction of the heart, and that all its motions can be heard, the thermometrical test takes nothing for granted without the most indubitable proof. Its great axiom is, that man in his living state maintains an uniform temperature independent of the surrounding media; while a dead man, like other inert matter, has no independence of this kind, but steadily responds to, and is governed by, caloric conditions altogether physical—heating and being heated, receiving and radiating caloric. This is not the result of speculation, but of prolonged and varied experimental research.

The refrigeration of the body before death in cholera, congestive, and the like, is not physical refrigeration responding to the caloric condition of the surrounding media; it is a morbid or physiological calorificity, which for a time augments or continues stationary after death, until it shall be replaced by physical refrigeration, as its phenomenal history clearly shows.

"The facts," observes Dr. Dowler, "which I have published concerning post-mortem calorificity do not invalidate this thermometrical test; for soon or late the physical refrigeration must take place. I may here add that the speculative opinion which pre-

vails among those who do not take the trouble to make experiments,—namely, that these calorific movements are the effects of putrefaction, is wholly unfounded (so far as it regards the human subject), how much soever it may be countenanced by certain analogies derived from other inert matter. The calorific and putrefactive periods, so far from coinciding, antagonize each other, so long as the heat is not in accordance with the ordinary physical laws of calorific. The point of coincidence and equilibrium is really the point of putrefaction, unless the circumstances be of an extraordinary character, such as involve the freezing point, or that of torrefaction. But the predominance of the invariable law of refrigeration is a criterion always attainable, and may be proved as to its times, distances, and velocities, by arithmetical calculation:—ascertain the temperatures of the media and of the heated body, the velocity of the refrigeration will be proportioned to the times and distances, and will proceed from the surface to the centre until the equilibrium be attained. The only objection that lies against this rule relates to the calorific conditions where the differences between the heated body and the media are very slight; but this is of no importance in practice, because there is always a marked difference between the average temperature of the air in the shade and that of a living or recently dead person.”—*British American Journal*, May 1850.

REPORT OF MEDICAL CASES OCCURRING IN THE NEW YORK HOSPITAL. BY V. P. COLTON, M.D., RESIDENT PHYSICIAN.

Case of Lead Paralysis.

MARCH 12th, 1850.—Henry Dorigan, *et. 28*, Ireland, clothier: is of sanguine temperament; has red hair, fair skin, and blue eyes. About six months ago he was seized with colicky pains in the epigastrium, which were quite severe, and which continued more or less acute for six days. His bowels at the time were quite costive: he took medicine, which produced free emesis and catharsis. In about half an hour from the accession of pain he began to feel a strange weakness in both hands and arms. Since that time he has had no return of pain; his bowels have been quite regular; appetite and general feelings have been natural; the weakness in hands and arms alone remains. At the present time the paralysis chiefly, if not entirely, affects the extensor muscles of hands and fingers, the flexors being about as strong as usual. A bluish tinge is observed along the edge of the gums. The only cause which a rigid examination can find to account for the symptoms is, the habit of drinking freely of

water, conveyed from a fountain half a mile distant through a lead pipe.

April 28th.—Has used internally, since his admission, Acid. Sulph.; Quin. Sulph.; Potass. Iod. Arms and hands have been freely rubbed with stimulating liniments, and fingers have been kept extended for a part of the time on the hand and finger splint; all without much benefit. Can use right hand rather more freely than when admitted. Discharged relieved.

Observation.—There would seem to be a peculiar tendency in many of the mineral poisons, in their remote effects, to produce cramps and paralysis of the second and third divisions of extremities—the face, arm, and hand, the leg and foot: and in several cases these affections have commenced in the fingers and toes, and travelled up the limbs. Thus, in a case of arsenical paralysis now in the Hospital, the pain, cramps, and paralysis commenced in the fingers of right hand; then in those of left; then in the toes, first of one foot, and, shortly after, in those of the other; the whole gradually extending up the limbs.

Another case of paralysis and cramps, from the chronic effect of arsenic, with similar phenomena, occurred here in 1847.

In lead paralysis, and in that produced by copper, the same order is sometimes observed. Also in a case of tremor mercurialis which lately fell under my notice: the weakness and peculiar trembling commenced in left fore-arm; then attacked left leg; then the right leg; and, lastly, the right fore-arm. The reason why the second and third divisions of extremities should be primarily affected, does not appear. It seems as if all cramps and paralysis proceeding from gastro-intestinal irritation showed the same preference. Cholera cramps certainly do; and the pain in the calves of the legs, in dysenteric patients, is a matter of daily observation.—*New York Journal of Medicine*, July 1850.

ON THE EMPLOYMENT OF NUX VOMICA IN IMPOTENCY AND SPERMATORRHEA.

DR. DUCLOS states that he has found the exhibition of doses of one-eighth to one-sixth of a grain of the alcoholic extract of nux vomica attended with beneficial results in cases of impotency resulting from long continence, and in those dependent on nervous excitability. In spermatorrhoea attended with general debility the nux vomica has produced an improvement of the constitutional condition, with cure of the spermatorrhoea. The dose above named is given three or four times a day, being gradually increased, even to the extent of two or three grains, without injury.—*L'Union Médicale*.

REMARKS.—The total number of deaths was 239 below the average mortality of the 36th week of ten previous years.

NOTICES TO CORRESPONDENTS.

Communications have been received from Dr. W. Hamilton, Dr. Addison, Mr. Lonsdale, Dr. Bucknill, and Mr. Bate (of Swansea). These will have early insertion.

We beg to assure Mr. W. J. Orr that his Essay, with six other works on Cholera, is now in the hands of a gentleman for review.

Lectures.

CLINICAL LECTURE
ON
CARDIAC DROPSY,
(Delivered at King's College Hospital.)

By R. B. TODD, M.D. F.R.S.
Physician to the Hospital.

[Reported by H. H. SALTER, B.A., Med. Schol.
K.C.L.]

LECTURE X.

GENTLEMEN,—In accordance with my two-fold plan of selecting for the subject of my remarks cases under your immediate observation, and at the same time giving you a consecutive account of the varied, allied, and contrasted forms of some particular disease (which one, as you know, at present is dropsy), I shall offer you to-day some observations on a case of *cardiac dropsy* now in the Fisk ward. The dropsy in this case is mainly dependent on heart disease; but there are present various other phenomena, which partly tend to complicate, and partly to elucidate the diagnosis, but which are all interesting and instructive in a high degree. These are pericarditis, renal disease, a congested state of the liver, dependent, no doubt, on the disease of the heart, and other slighter pathological conditions, which I shall advert to in the history of the case.

The patient, Alfred Baylis, is a young man, *æt.* 30. His occupation has been that of a housepainter, a most unhealthy one, and he bears, in the blue line round his gums, the badge of his trade. Like many of his occupation, he has been intemperate in his habits; and to this, most probably, his present condition is mainly referable.

He was admitted on the 11th of November, suffering from palpitation, shortness of breath, and emaciation, which quickly supervened upon an attack of hæmoptysis to a considerable extent, that occurred two months previously. He had been an out-patient of one of the hospitals in town; and five weeks before his admission here dropsy of the lower extremities came on, and has been steadily increasing ever since. Under these circumstances he applied for admission. Shortly afterwards he suffered another and very violent access of hæmoptysis. These two attacks of hæmoptysis have produced great pallor and anæmia; and at the same time the patient

is suffering from distressing dyspnoea, amounting to *orthopnoea*. Upon any attempt to assume the recumbent posture he is at once compelled, by the increased difficulty of respiration, to sit up, and in this posture, as you may have remarked, he remains day and night. This orthopnoea has been from the commencement a prominent symptom.

The great loss of blood which he has suffered has given rise to another symptom, —amaurosis: this seems to vary with the condition of the heart. When he suffers much from palpitation his sight is worse; when the palpitation is less it is better; showing the dependence of the symptom on the state of the circulation. The fact is, the blood has become poor, and this impairment of quality causes any slight deficiency in the quantity sent to an organ, from inefficient action of the heart, to be felt by it more readily than if the blood were in its normal state. Associated with this symptom is another curious one; namely, a remarkable prominence of the eye-balls. I mention it because it seems to have some connection with cardiac disease. I have seen it particularly in women. I have also met with it in connection with enlarged thyroid gland. The cause of these associations I do not attempt to explain.

In looking into the previous history of our patient, to ascertain if there be anything to explain the existence of cardiac disease at so early an age, we can only find that at the age of 19 he suffered a slight attack of rheumatism. We can get no distinct evidence that the heart was at that time affected: but it is highly probable that, at the same time with the rheumatic attack, there took place some slight organic affection of the heart, either pericardial or endocardial, which his subsequent unhealthy occupation and intemperance have tended to increase.

His state on admission into the hospital was as follows:—Great exsanguineousness; breathlessness, particularly orthopnoea. Heart's action natural and regular, with no preternatural impulse; pulse 84, small, regular. There was an unnatural extent of dullness over the region of the heart, and moreover the pulsations of the heart were visible and sensible in the region of the scrobiculus cordis: they were felt also in the cardiac region. In some cases the heart's action is felt only in the scrobiculus cordis, and beneath the left mamma; and in such there is no evidence of enlargement; for there may be, and probably is, some cause pressing the heart to the right side, so that the altered seat of the pulsations is due to change in the position of the entire organ. But when the pulsation of the heart is felt in both regions we have evidence of

enlargement, and of its being, at least, the right ventricle that is enlarged; for while the left remains stationary in its normal situation, the right has passed over still further to the right side. Those of you who accompany me regularly through the wards of the hospital may notice, that in all cases of dyspnoea I make it a rule to place my hand over the scrobiculus cordis to feel if I can detect any cardiac pulsations there. My attention is particularly directed to this point in cases of long-standing asthma, and rarely in these cases do I fail to find it; never, indeed, if the asthma have produced emphysema, where there is not only displacement of the right ventricle by hypertrophy, but a pushing of the whole heart to the right side from the enlargement of the lungs.

We noticed also in this case a friction sound accompanying the systole and diastole, heard below and to the left of the nipple, and very circumscribed in extent. There was no bellows murmur either at base or apex; but we observed a phenomenon, connected in its indications with the beating of the heart, in the scrobiculus cordis,—viz., venous pulsation in the neck. This man has very large jugulars, and you may see them pulsating distinctly even at some distance from the bed. This phenomenon, as you know, is due to a reflux of blood at the systole from the ventricle through the auricle into the venous system. In consequence of the obstruction in the lungs the ventricle cannot completely empty itself, and so becoming distended the tricuspid valve allows some of the blood to regurgitate, and thus to escape through the auricle into the veins. The proper source of supply to these veins is from their distal extremity. If then you put your finger in the course of that supply,—that is, to the distal point where the pulsation is observed,—the vein would, if healthy, become empty; but it does not; it continues full, and its pulsations persist: hence the waves of blood which produce the phenomenon of pulsation must be propagated from the cardiac extremity of the vein. There are many cases of heart affection where there are no pulsations, but where the vein does not empty itself on the cardiac side of the point pressed. Now in such cases there is regurgitation, but not to a sufficient degree to cause the pulsation. In perfect health the vein will be quite empty below the point pressed: but it is possible that a slight enlargement may suffice to produce the opposite state; and it is very possible that, even in health, it may exist to a slight extent under the prolonged though temporary occurrence of some disturbing circumstances, such as great efforts, violent actions, &c. When the regurgitation

exists in a great degree, you may see all the superficial veins of the neck and chest pulsating.

We found also in this case evidence of great pulmonary congestion, crepitus and rhonchus being heard over various parts of the chest; and there was abdominal dropsy, caused by obstructed circulation through the liver. On examining the urine we found it acid, of specific gravity 1015, and heat and nitric acid gave evidence of the existence of albumen. When the fresh urine was allowed to stand, a scanty and flocculent deposit was formed, which, under the microscope, was found to consist of blood-corpuscles, epithelium (chiefly renal), a few pus globules, and a great many casts, for the most part granular and transparent, some containing cells loaded with oil globules; but these were not very abundant. Now this is a state of things which we should fancy our patient would not be likely long to survive; yet here we see him remaining very much in *status quo*, if any thing a little improved, until the present time, Jan. 1863, a space of two months.

Let us now analyse these symptoms more minutely, and see their nature and indications, and what conclusions we can deduce from them.

The *palpitation* was no doubt an irregular rate of action. When the heart beat quickly he had what he called palpitation; when more slowly, the palpitation ceased. When patients speak of palpitation they often mean different things; sometimes they signify by it deranged rhythm, either complete intermission, or irregularity of action; and sometimes, as in the present case, an increased rate of action without any derangement of rhythm. Our patient has not suffered from any remarkable rapidity of the heart's action, except in the above temporary way.

Orthopnoea.—This is almost always connected with imperfect circulation through the lungs: but this imperfection of the pulmonary circulation may either be primary, as in asthma, or secondary, from imperfect action of the heart. In asthma no doubt there is, frequently, an anatomical change in the lungs; but we must guard against the idea that this is essentially the disease: the primary affection is in the nervous system, or in the digestive organs, or both, and any irritation there will produce the asthmatic spasm. But this state of spasm may give rise to anatomical change of the lungs (emphysema); and its frequent recurrence is sufficient to render such a state to a certain degree permanent. When the heart is primarily affected, the embarrassment of the respiration, which is secondary, has received the name of cardiac asthma.

In connection with this we found a *state*

of congestion of the lungs. Now this no doubt was dependent on the heart, through the imperfect action of which the blood was thrown back on the lungs. To this the hæmoptysis is to be attributed; and no doubt, if we could examine the lungs, we should find the remains of pulmonary apoplexy, and of rupture of pulmonary vessels, in the characteristic currant jelly-like spots.

The beating of the heart in the scrobiculus cordis, and its interpretation, I have already referred to.

The *dropsy* is a result of which I shall say more by and by.

Diagnosis.—Now can we, from these general symptoms, make a diagnosis without reference to the physical signs? I think we can form a diagnosis which shall be sufficient for all practical purposes; and I recommend you, as an important exercise, to endeavour to diagnose from symptoms before you have recourse to auscultation; because by so doing your attention will be directed to the disturbed *functions*, and you will thus receive important suggestions for treatment. Those who direct their attention exclusively to physical signs are apt to overlook these derangements of functions, and therefore miss some valuable indications of treatment corrective of them.

Now if I were to proceed on the data afforded by the *general* symptoms alone in this case, I should diagnose first, *dilatation of the right side of the heart*: the pulsations of the jugulars, and the beating of the heart in the scrobiculus cordis, both indicate this. The pulsation of the jugulars, if proved to be regurgitant, is conclusive evidence of dilatation of the right ventricle: no other condition of heart is capable of producing this phenomenon. But we must be careful to prove that the venous pulsation is regurgitant, as it may be due to other causes: it may depend on the impulse of the heart being transmitted through the capillaries; or it may depend on the contiguity of a large artery which communicates its pulsations to the adjacent vein; therefore we must be careful in proving its nature before we attach importance to its indications. Now, by making pressure on the vein, we obtain sufficiently conclusive evidence as to the nature of the pulsation. If the vein empty itself on the cardiac side of the point pressed, and yet the pulsation continues in the empty portion of it, we know it arises, with the highest probability, from some contiguous artery; and this conclusion is rendered certain, if the pulsation ceases on stopping the circulation in the artery. If, on making pressure, the pulsation continues only on the distal side of the point pressed, we may infer that the pulsa-

tion is due to the transmission of the pulse from the heart throughout the circulation, and especially if it be perfectly synchronous with the heart. But if the vein continues full between the point pressed and the heart, then we know, whether there be pulsation or not, that that vein must receive blood from its cardiac side, and this it can only do by regurgitation from the right side of the heart.

You are doubtless aware that a slight regurgitation always takes place from the auricles into the veins in the normal state, and that that regurgitation is synchronous with the auricular systole. But when the ventricle and auricle are dilated, the amount of regurgitation is increased in proportion to the degree of dilatation of the cavities: blood regurgitates from the ventricle into the auricle, and from the auricle into the veins.

The beating of the heart in the scrobiculus cordis is also indicative of dilatation of the right ventricle, because by its dilatation that cavity extends to the apex, and the apex thus enlarged extends to the scrobiculus. But, before we can affirm that the beating of the heart in the scrobiculus is due to the dilatation of the ventricle, we must be careful to ascertain that there is no displacement of the heart, which may be easily determined by seeing that its impulse is felt in the normal, as well as in the abnormal, region.

So far, then, we may affirm, that there is dilatation of the right side of the heart. But such a lesion as dilatation does not arise spontaneously. There must be some dilating force, and that force is the backward pressure of the blood. When the muscular tissue of the heart is in a weak state, we can conceive that the walls of the ventricle may yield readily, without supposing any great increase in the ordinary pressure of the blood. But, in general, dilatation arises from some obstacle to the flow of blood from the ventricle; and in proportion to the resistance which that obstacle affords will be the backward pressure of the blood on the surface of the ventricle,—in other words, the amount of obstacle will give the amount of dilating force. In every case of dilatation of one of the heart's cavities, then, you must look for this dilating force,—this obstacle; and you will find it either at the orifice through which the cavity expels its blood, or in the arteries, or in the capillaries of some important organ, or in some defect in the valves or the orifices of the heart. Dilatation of the right cavities of the heart rarely arises from diseases of their own orifices; for obstructive disease of these orifices is amongst the rarest of cardiac lesions. Experience tells us that the obstructions which the right ventricle

has to encounter are either from the circulation through the lungs, or from some derangement of the circulation through the left side of the heart.

And there is another cause which may produce dilatation as well as hypertrophy of the right ventricle, because it may produce the same change in all the cavities of the heart; that is, extensive or universal adhesion of the opposed surfaces of the pericardium. How it happens that obliteration of the pericardial sac can produce these changes, I do not attempt to explain; but that it does so, there can be no doubt.

Let us now inquire what may cause a dilated right ventricle in this case. I have said that the most common causes of dilatation of the right ventricle are obstructed pulmonary circulation, or obstructed circulation through the left side of the heart. The most common causes of obstructed pulmonary circulation are the asthmatic state, or that which is a frequent consequence of the asthmatic state—emphysema of the lungs. We have no indications in this case of either of these conditions. The history of the patient shows the absence of the one, and the physical signs demonstrate the absence of the other. Is there, then, any disease of the left side of the heart sufficient to create this dilatation?

When I saw the patient first I hazarded a guess, from the character of the pulse, that there was *mitral* disease at the foundation of his malady. The peculiarity of pulse which suggested this notion was, that it was small, produced by a small stream, apparently inadequate to the size of the artery, and not proportioned to the action of the heart. Such a state of pulse does frequently co-exist with mitral disease; but so various are the conditions capable of producing a small feeble pulse, that a diagnosis based upon that sign only must necessarily be only a guess. Now such mitral disease might be either *regurgitant* or *obstructive*,—either of the two would affect the right side of the heart. And how?—By affording an obstacle to the return of the blood from the lungs. Whether the blood is unable to advance in consequence of a *contracted* mitral orifice, or whether it flows back in large quantity into the auricle, it is evident that an impediment is offered to its passage from auricle to ventricle, and, therefore, to its return from the lungs to the auricle; and when this has continued for some time, the right ventricle being exposed to a degree of pressure greater than customary, yields, and gradually expands, till at length it assumes a permanently dilated state.

Now, is the disease here *regurgitant* or *obstructive*? The dyspnoea favours the idea that it is *obstructive*, because there is

no form of heart disease in which the dyspnoea is so great as in obstruction at the mitral valve. Very often, when the disease is of this nature, sudden and terrible dyspnoea is the first evidence of its existence: the patient is suddenly awoken out of sleep by a breathlessness that seems as if it would kill him: he starts up in bed and gasps for breath till the paroxysm gradually subsides. Such a first attack is generally the precursor of similar ones, increasing in severity and frequency, only kept off by constant watching and the upright position, till at length the dyspnoea becomes constant, and the case terminates with pulmonary apoplexy.

But in the absence of this disease of the mitral valves, is there any other way of explaining the occurrence of the dilatation of the right cavities of the heart? The only explanation I can offer is that there is hypertrophy and dilatation of the left cavities connected with obstruction in some part of the systemic circulation, in the aorta or in the renal circulation, or dependent on adherent pericardium, and that this state of the left cavities obstructs the circulation through the right cavities, and causes dilatation and hypertrophy of them.

So far, then, for the indications afforded by the general symptoms: let us now turn to—

The physical signs.—A careful observation of the physical signs will serve to confirm or correct our inferences from the symptoms, and help us to adopt a more decided diagnosis. The physical signs themselves were these: extensive dullness over the præcordial region, indicating enlargement of the heart; the first and second sounds were found to be essentially healthy, and unaccompanied with bellows murmur, as well at the base as at the apex. The absence of bruit at the base shows that there is no aortic disease; also its non-existence at the apex shows that there is no *regurgitant* mitral disease; for if there were, we should inevitably hear a systolic bellows murmur in this situation—*i. e.*, unless the heart's action were very weak: it is only in a state of great feebleness of the ventricular contraction that there would be no bellows sound where there is mitral regurgitation; but with our patient the heart's action is not at all feeble. Now, is there any diastolic bellows sound to indicate obstruction at the mitral orifice? We find none. Are we, then, justified in denying the disease of the mitral valve? Certainly we are not, for those cases of unquestionable obstructive mitral disease in which a diastolic murmur is heard are comparatively few: there must be a certain amount of force in the auricle for its production, and unless this exists the sound will not be heard.

The value of this evidence, therefore, is merely negative: it does not prove that there is no obstruction at the mitral orifice, but only that the impulse given to the blood by the auricle is not sufficient to elicit a sound from the existing obstruction. So far, then, we receive really no aid as to determining the question of the existence of obstructive mitral disease from examining the sounds of the heart. We know, however, that there is no mitral regurgitation; and, as to the question of mitral obstruction, we have no further evidence than what the symptoms give us.

This evidence is undoubted as to the existence of obstruction; but it is not sufficient to determine the exact seat or nature of the obstruction. By the aid of auscultation we can determine that it is not mitral regurgitation: it may, however, arise from contraction of the mitral orifice, or from that general obstruction which the left heart has to encounter in the distal part of the systemic circulation.

Taking it for granted, then, that the circulation through the left side of the heart is obstructed, it is easy to explain all the other symptoms. The obstruction through the left side of the heart throws the blood back on the left auricle, and thence on the lungs, giving rise to the state of extreme pulmonary congestion in which we find our patient, and the consequent hæmoptysis. The obstruction at the lungs is felt by the right ventricle, which, in its efforts to overcome the opposing obstacle, becomes dilated and hypertrophied: the right auricle encounters corresponding difficulties to those which oppose the action of the ventricle, and it becomes similarly dilated and hypertrophied; and, in consequence of the impediment which it has to encounter, the blood is thrown back upon and delayed in the venous system, and regurgitant venous pulsation and dropsy are the result. Thus we see all the symptoms fall in a retrograde succession, as the consequences of the obstructive force beginning at the left side of the heart, or in some part of the systemic circulation.

A feature of this case which practically is of most interest to us is the *dropsy*, because this is the symptom which generally and justly excites the most alarm in the minds of patients and their friends. I have already mentioned that the characteristic of cardiac dropsy is this, that it always takes place in the most dependent parts: it does not begin, as we have seen other forms of dropsy, in the face and upper extremities. An aneurism may cause dropsy of the upper parts of the body from pressure on the descending cava or some of its large tributary veins, but pure cardiac dropsy never comes on thus: the

very fact of its not existing in the upper parts of the body indicates its cardiac nature. We find it apt to vary in amount according to position; the erect or sitting posture favours its accumulation, and hence we find it in increased quantity towards the end of the day, and disappearing or diminishing in the morning from the recumbent position during the night. Still, it *will* appear in the upper extremities, but always late, and often more on one side than another, being most abundant on that side which is the most dependent. This we have seen in our patient: his left hand was the first affected; but lately we find he has been lying very much on his right side, and the consequence is that the dropsy has left his left hand, and accumulated in his right. We could not have a better proof than this of the purely mechanical character of the effusion.

Now what is the immediate cause of this dropsy? We have seen that the obstructing force extends from the left to the right side of the heart, and by its influence in the latter situation a considerable portion of the blood returning from the general circulation is pumped back into the veins at every systole: this obstructs the flow of venous blood throughout the body: the circulation is consequently impeded in the capillaries: these vessels become loaded, and the only relief they can obtain is by the filtration of the serum of the blood, or the liquor sanguinis, into the areolar tissue. If any part is dependent, a greater force is needed to send the blood through its capillaries, because the venous blood has to ascend against gravity: a greater accumulation is apt to take place both in the capillaries and veins; and, therefore, such part becomes affected with a greater amount of dropsy.

The access of dropsy is always a serious symptom, but not necessarily a fatal one. It may come on early or late. In some cases of purely cardiac disease in young persons, not complicated with either kidney or liver disease, dropsy may come on early, from which the patient may recover completely, and life may be prolonged for some time even although the cardiac disease continue. Suppose a patient has had rheumatic endocarditis, and that the impairment of the mitral valve gives rise to regurgitation, the effect would be to obstruct the circulation first at the left, and then at the right side of the heart. Now the right cavities feel the obstruction at first much more than they would do afterwards: the left auricle, being slow to dilate, has not yet adapted itself to the deranged condition, and the whole force of the obstruction is thrown back on the lungs and on the right side, the cavities of which dilate

easily, and you get rapid dropsy. In the meantime the left auricle dilates, the circulation through the lungs becomes less obstructed: there is, therefore, less obstruction in the right side of the heart: it gradually recovers itself, and the dropsy diminishes.

In all cases what seems to be necessary to the production of the dropsy is the *dilatation of the right side of the heart*. I think my friend Dr. Blakiston, of St. Leonard's, was the first to point out clearly the importance of this condition. Dr. Blakiston seems to lay it down as a rule that venous regurgitation always precedes the dropsy. But dilatation may exist without regurgitation being manifest in the external veins: at least, I think that the regurgitation need not exist to such a degree as to produce pulsation. I am now attending a case in private practice in which there is dropsy and undoubted dilatation of the right side of the heart, but no venous pulsation.

But there are certain other circumstances in this case, in addition to the condition of the heart, that predispose to dropsy: these are, a state of the blood in which the water is in large proportion, and its solid ingredients defective, and *renal disease*. When the blood is in such a condition as to favour dropsy, the other causes will act much more speedily than when such is not the case; and, no doubt, in the present instance, the dropsy came on much earlier in consequence of the impoverished state of the blood occasioned by the repeated attacks of hæmoptysis which our patient had suffered.

Reviewing, then, the whole case, we may sum up thus: that the primary cardiac affection consisted in a rheumatic endocarditis, which narrowed the aperture of communication between the auricle and ventricle, and thus obstructed the passage of the blood into the ventricle, throwing it back upon the lungs, causing pulmonary hæmorrhage, and dilatation and hypertrophy of the right cavities; or, in a rheumatic pericarditis, causing an extensive adhesion between the heart and the pericardium, and so far impeding the heart's play as to give rise to hypertrophy with dilatation of its cavities. Or that, from some obstruction to the circulation, either in the large arteries, or in some more distant part of the circulation (in the kidney, for instance, from the chronic disease in that organ), the left heart has suffered dilatation and some hypertrophy; and that, in course of time, the right heart has, in consequence of the obstructed circulation in the left side, become hypertrophied and dilated likewise. On the former supposition, the primary disease would be in the heart itself;

on the latter, it would be in the kidneys, or some other part of the systemic circulation.

I have already alluded to the amaurosis with which our patient is affected. This affection most probably results from an anæmic state of the retina. Last summer we had in the hospital a remarkable case, which illustrated how loss of blood produced amaurosis. The man had suffered from violent hæmatemesis: after the last attack he completely lost his sight, and he remained quite blind afterwards, notwithstanding a variety of treatment to which he was subjected. In a case of this kind the nutrition of the retina is permanently damaged by the altered quality or quantity of the blood after such severe hæmorrhage, and it bears an analogy to those cases in which delirium or epilepsy follow excessive losses of blood, or extreme states of anæmia.

One thing I have omitted to mention, and that is the pericarditis. At the time of our patient's admission there was a very distinct rubbing sound over the region of the heart, which the next day had disappeared, and with its disappearance aggravated dyspnoea, an undulating movement in the region of the scrobiculus cordis synchronous with the action of the heart, increased extent of præcordial dulness, and feebleness of the cardiac sounds, supervened. We set down all these signs to the development of a large quantity of water in the pericardium; and, with the idea of getting rid of it, I applied a blister over the region of the heart, preceding it by a mustard plaster, and purged him well, supporting him at the same time with chloric ether. The good effect of this treatment was manifested by the disappearance of the symptoms just named, and the return of the rubbing sound. Now what was the cause of the pericarditis? This is very doubtful; but this we know, that renal diseases are very apt, by the contamination of the blood by the uneliminated urinary principles, to induce serous inflammations, and that this man was, at the time of the attack of the pericarditis, labouring under such renal disease.

Treatment.—In the treatment of cases of this description your attention should be principally directed to the relief of the urgent symptoms, and to strengthen the power of the heart. For the relief of the dropsy a great deal may be done by attention to the position of the patient, and by the administration of diuretics. With the view of supporting his power we gave our patient Baylis tonics and iron; and, finding the kidneys acting imperfectly, we gave him digitalis. But in such cases it is desirable to be careful in administering this medicine, and it is a good plan to combine it with some tonic. I frequently combine it with

anæmia, or give the tincture of digitalis with the tincture of muriate of iron. However, I cannot say that any great benefit resulted in the present case, either from the digitalis or the iron: that treatment was cut short by the supervention of the pericarditis. This, however, was subdued by very simple means—counter-irritation and copious discharge by the blister.

There was much difficulty in getting the kidneys to act, and the greatest benefit was derived from the bitartrate of potash, either alone or in combination with the pulvis jalapæ, or the compound powder of jalap. We also gave him him lemon-juice, and found it acted freely on the kidneys for some time. The dose of lemon-juice was from half an ounce several times a day.

Elastrum was also given, but without any decided benefit. What, however, has served best to keep down the dropsey of the legs is the acupuncture: the quantity of water that has run away from him, and the relief that he has obtained from it, is surprising. In practising acupuncture in dropsical cases it is important that you should make the punctures at a considerable distance from each other, for each puncture is apt to become the centre of an erysipelatos inflammation, which spreads the more readily when the punctures are too near each other. Indeed, however you make the punctures, the difficulty which you have to encounter arises from this erysipelatos inflammation, which almost invariably follows sooner or later. There is another method of relieving anasarcos legs, lately proposed by Lombard, of Geneva. Instead of pricking the legs at various points with the needle, he advises to make a single incision above the inner malleolus, or in some other convenient position (not too near a vein or artery), cutting through the skin and subcutaneous tissue down to the fascia. The length of the incision may be from half an inch to an inch, and the rapid flow of water that these incisions admit of is further encouraged by sitting the patient on the side of the bed for a certain time during the day with his feet placed in a tub. The patient has by this means the treble advantage of increased rapidity of the flux of the fluid, the prevention of that sloppy and soaking condition which inevitably ensues when the acupuncture are running all day, and the ease to the breath that results from the erect position. There is less danger of sloughing by this process, as a single incision is enough for each leg. If this man does not materially improve soon, we shall adopt this system, and then you will have an opportunity of seeing its effects.

Unhappily we can do nothing to restore the impaired action of the heart, but we

may do much to ameliorate the condition that that impairment entails. The principal indications are to support the patient's strength, to keep open the emunctories, and to adopt all the means in our power to get rid of the superfluous water.

CRIMINAL ABORTIONISM IN NEW YORK.

THE Report of the City Inspector for 1849, shows a large increase in the number of premature and still births.

"In three years we have a mortality from premature births of 400; and from still-born of 3,189; making a total of 3,589 (!) human beings that never breathed.

"Since 1805, when returns were first made to this office, the number of these accidents has steadily and rapidly augmented. With a population at that time of 76,770, the number of still-born and premature births was 47; in 1849, with a population estimated at 450,000, the number swells up to 1,320! Thus, while the population has increased nearly six times since 1805, the annual number of still-born and premature births has multiplied over twenty-seven times!

"The following table shows the rapidity of this increase:—

In 1805 the ratio to population was		
as	1	to 1612.18
1810	1	" 1025.24
1815	1	" 986.46
1820	1	" 654.52
1825	1	" 680.68
1830	1	" 597.60
1835	1	" 569.88
1840	1	" 516.02
1845	1	" 384.68
1849 (estimated)	1	" 340.90"

The facts thus exhibited demonstrably furnish proof that causes have been at work in this city during the last few years, and are steadily increasing, in a frightful ratio beyond the increase of the population, not merely but wholly inexplicable on any principles which do not recognise an amount of guilt at which humanity shudders. The city inspector indicates the truth when he says:—

"This is a state of mortality from these accidents truly alarming, which, while no remedy can be advised, demands our most serious consideration. What of crime and recklessness there is in this sum dare not be expressed, for we cannot refer such a hecatomb of human offspring to natural causes. An honest and fearless expression of the causes or circumstances attending these events, on the part of the medical attendant, would bring into this department an amount of valuable knowledge that might be useful in checking this horrible and increasing waste of life."

Original Communications.

ON THE
CONTAINING-TEXTURE OF THE
BLOOD.

By WILLIAM ADDISON, M.D., F.R.S., &c.

[Continued from page 321.]

In what texture is inflammation seated? If we examine any soft part of the body, we find it composed of parenchymatous substances (nerves, muscles, and secreting substances), intermixed with blood-vessels and sundry forms of fibrous texture.

§ 1. *Of the parenchyma of different organs.*—The particular substances of different organs, as a consequence of the order of development in the embryo (p. 193), become placed outside the blood-vessels, disposed in groups or masses in the interstices between them. These divide themselves, by their physiological offices or functions, into three well-marked classes—*sentient*, *motor*, and *secreting*; which again, upon physiological grounds, are variously characterised and subdivided. Thus, of the *secreting organs*, the parenchymata and secretions are extremely different; of the *muscles*, some are voluntary, others involuntary; and, in the *nervous system*, the physiology of sentient elements differs in each of the organs of the senses. Those of the ear have a very different function from those of the eye, and so on. But let us review generally the plan of the conformation of the body, with reference to the parenchymata of different organs, in as far as they have relation to inflammation. That which appears simple to the unaided vision becomes exceedingly complex examined microscopically.

The skin and mucous membranes are *secreting organs* so much unfolded and spread out, that the parenchymatous substances upon which the secreting actions depend become disposed in distinct spots or groups, each with its separate outlet or duct, the intervals between being filled in with a corresponding development of fibrous tissue. On the contrary, in the internal secreting organs, the groups or lobules of the parenchyma are so closely folded toge-

ther, that not only is the bulk of the organ very greatly increased, but the ducts unite many times; forming a series of coalescing larger and larger tubes, which demand for their conformation and support a constantly-increasing thickness of dense fibrous texture, the submucous fibrous basis. But then, that no space may be sacrificed, all the lax areolar forms of fibrous tissue are reduced to the smallest possible compass that is consistent with the magnitude and requirements of the secreting mass.

Passing from the secreting parenchymata to the organs of purely animal life, we observe correspondent groupings and relations. *Muscular fibrillæ* (sarcous elements) are associated in great masses in the voluntary muscles, having between them the smallest possible amount of fibrous inter-divisions. Elsewhere the fibrillæ are spread out in thinner sheets, with a larger proportion of fibrous areolar tissue intervening; and in other places unstriped fibrillæ are distributed in almost single threads.

Sentient elements are congregated in prominent and distinct spots, termed *papillæ*, in the skin. They are exposed in thin and delicate sheets upon the organs of hearing, sight, and smell; but in nerves, spinal cord, and brain, they are folded and disposed within the smallest space. It is to be observed that, for the most part, the elements of the special parenchymata retain through life the cell-form. The prominent exceptions are *medullary tubules* belonging to the nervous, and *sarcous elements* belonging to the muscular system. These in the embryo, and for some period of foetal life, are represented by cell or germ-forms; but during growth there is a metamorphosis to the forms by which they are afterwards recognised. Nerves and muscles, therefore, are not primary but secondary forms; and these appear to re-unite after division, provided their dis severed ends be brought sufficiently near together. But this reunion, or rather incorporation, of medullary tubules and muscular fibrillæ, after division by cutting, does not appear to be a phenomenon of repair by the metamorphosis of lymph, but to arise from inherent properties in the substances themselves—a sort of out-growth of nerve and muscle substance: for, first, it does not seem to take place, except during youth; when, as we have remarked, growth is mingled with repair;

and secondly, when it does occur it is only some time after the process of repair as it relates to fibrous texture, or the formation of the cicatrix, has been concluded.

Now the elements of the particular substances of different organs cannot inflame, except in the meaning of secession, absorption, or disappearance, before new and interpolated forms, or of being intruded upon and deranged by the effects of inflammation. Correctly speaking, upon the testimony of microscopical analysis, inflammation is not seated in brain-substance, liver-substance, or muscle-substance; though we speak of such in consequence of the microscopic character of their relations to blood-vessels. No lengthened argument is needed by those accustomed to microscopical observation, to prove this with respect to the cell-particles and medullary tubules peculiar to the nervous system—the fibrillæ, or sarcoous elements of muscles, or the secreting cell-particles of the liver, kidney, and other secreting organs. But if the elements of the parenchymatous substances of different organs do not inflame, inflammation must necessarily be seated in the fibrous textures.

§ 2. *Of the fibrous membranes, fibrous textures, and areolar tissue, skin, and mucous membranes.*—What are the relations of the fibrous membranes?—are they correlatives of blood? Large venous sinuses from the brain traverse the *dura mater*, which are described by anatomists as situated between its laminæ, because of the perfect homogeneity of the elements of the coats of the sinuses and the rest of the membrane. The strength and thickness of the *dura mater* have an evident relation to the magnitude of the blood-streams it conveys. The blood-vessels of the *pia mater* are much more numerous and much smaller, and the membrane is in a corresponding degree thinner and more delicate. There is here the same species of fibrous elements in the coats of the vessels, and in the non-vascular parts stretching in the intervals between them. The *pericardium* is a thick fibrous membrane resembling the *dura mater*, and, like it, coincides in strength and thickness with the magnitude of the great vessels from which it is, as it were, reflected to cover and protect the central moving point of the circulation. The *areolar tissue* is one of the most ex-

tensively diffused of all the elements of organisation. So comprehensive is the association of this tissue with the blood-vessels, that it would be difficult to point out a single instance in which they are not enveloped by it. Even the capillaries of the coats of the larger vessels are invested by a sheathing of this tissue. The *cutis*, or fibrous basis of the skin, cannot be distinguished from areolar tissue except by the greater condensation and more intricate interweavement of the fibrous elements. "However great the difference may seem to be between the dense and closely-woven texture of the *cutis* and the lax areolar tissue, to which it owes its mobility on subjacent organs, they blend insensibly together. Their ultimate texture is essentially the same."* The same may be said of the fibrous basis, or the submucous fibrous tissue of the mucous membranes, excreting ducts, and tubes. This blending insensibly together of the different modifications of fibrous tissue furnishes the grounds of an affirmative answer to the question proposed. And such an answer harmonizes with the pathological facts—viz., the completeness with which all the phases of inflammation are exhibited in fibrous membranes: increased vascularity, lymph-growth, granulation, and pus, as belonging to the primary stage or proximate form; and adventitious fibrous texture of every degree of laxity and condensation, and ossification, as the secondary or more remote. But an affirmative answer embraces a very extensive class of textures. What, therefore, is the history of the growth of fibrous membranes? During growth in the embryo, all the fibrous textures appear from our researches to follow, *pari passu*, the phases of the coats of the blood-vessels. When the latter are corpuscular, the former are corpuscular also; the fibrous type is coetaneous in each. In their growing state these textures are not only greatly more cellular, but also greatly more vascular than when their fibrous type is concluded,—a fact which corresponds in a very striking manner with the cell-structure and high vascularity of "granulations," as compared with the low vascularity and fibrous structure of the "cicatrix." By these facts we trace relations not only between the cell and

* Pathological Anatomy, by Dr. Todd, F.R.S., and Mr. Bowman, F.R.S.

fibrous types of the blood-vessels and the growth of fibrous membranes, but also between these and the granulations and cicatrix of a burn—i. e., between growth and the first and second periods of repair—the rise and cure of inflammation; so that, whether it be that condensed form of fibrous tissue which, limiting and transmitting the streams of blood, we call blood-vessels,—or that closely woven form which backs and supports the glandulæ and papillæ of the skin and mucous membranes,—or that expanded membranous form which incloses the various parenchymata,—or, lastly, the lax and areolar form which admits of motion between contiguous parts, all are subject to the same pathological law: that is to say, the fibrous textures are the theatre of the morphological properties of blood (of repair, inflammation, and scrofulous disease), because they are correlatives of blood.

Thus we arrive at the full meaning of the terms we have employed to head the present inquiry,—*the containing-texture of the blood*,—a meaning not limited to blood-vessels, but comprehending with them all the variously modified forms of simple fibrous tissue. And we have been encouraged and led on to this comprehensive meaning step by step in our researches, considering that inasmuch as the very small vascularity of a tough fibrous cicatrix does not affect its relations to the previous highly vascular cell-granulations, and through these to the elements of blood, so it appears the small vascularity of a tough and condensed, or lax and areolar form of any original fibrous membrane does not deprive it of its physiological correlation and *consanguinity*.

§ 3. *Of inflammation, the first period of repair, abscess, ulceration, and organic disease.*—Inflammation to the ordinary observer appears as a phenomenon of redness, heat, swelling, and pain. To us it appears as a phenomenon of change or *morphology*, affecting, and limited in its definitive character to textures, correlatives of blood in which *cells and cell-growth supplant fibrous forms*. This definition of inflammation is founded upon the facts which have been discussed, and is corroborated by the distinctions recognised by all of us between congestion, hyperæmia, blushing, and inflammation. In the former the coats of the blood-vessels do not experience any morpho-

logical change or essential alteration of type. In the latter they do; the change from fibres to cells adapting them to the supply of new vessels, and to the support of new growths (p. 318).

Whatever be the view entertained by different pathologists respecting the nature of inflammation, whatever the definition they may deem most appropriate, and whether they regard it in its benign and physiological aspect as the first period of a *process of repair which is to follow* (p. 317), or in its morbid aspect as a destructive process, there can be no possible doubt about the appearance or accumulation of cell-forms—termed *lymph-particles*—upon and around the blood-vessels; nor, looking to the general history and physiology of cells in every department of the animal and vegetable kingdoms, do we think there can be any reasonable question raised as to the lymph-particles being, in the examples we are reviewing, the agents which determine the observed changes, which disintegrate and supplant, or *absorb* the fibrous texture in abscess and ulceration. Lymph-particles cannot inflame. These, as we have before said, are microscopic whole organisms, and as such liable themselves to *inherent deteriorating changes*, which modify their character as physiological and pathological agents, diminish their co-ordinated vital properties, and cause them to appear under sundry microscopic aspects, as exudation-cells, pus-particles, &c.

Thus it seems to be the deteriorating changes in the constitution of the cell-particles, in the example of chronic scrofulous abscess already referred to (p. 318), that retard and render chronic, scrofulous, and incomplete, an action which, had the cell-particles been plump, vigorous, and healthy, might have proved simple inflammation followed by the cure. Weakness, incapacity, and death, in the agents of an operation, stop the work, and lymph-particles, which are irregular and effete, render inflammation chronic, and cure tardy. If the microscope brings us physiologically to a point where the vital energies of cell-particles are the necessary antecedents of fibrous structures, so it brings us pathologically to the same point in interpreting the phases of repair and inflammation. *And, as in growth in the embryo, every fibre taking the place of a cell-particle is an element in natural development contributing to the concluded or adult form of fibrous tissue;*

so conversely, when fibrous textures have been established, every cell supplanting a fibre is an element of retrograde metamorphosis; and according to the conditions of the supplanting cells does this assume the physiological, or degenerate to some pathological aspect.

It is the pre-established, the seceding fibrous coats of the blood-vessels, to which we refer as the seat or subject of inflammation: and as regards them in the first instance, the action is the same whether it leads to repair or ulceration, the difference arising in the one case by normal fibrous forms asserting their supremacy; in the other, by the primary cell-action pursuing an unchecked course. The reasons of the difference is the field of speculation (p. 319). Our conclusions are, that textures correlative of blood are the seat, and lymph-particles the material agents; repair, inflammation, and scrofulous disease, the phenomena.

But though the elements of the parenchymatous substances peculiar to different organs do not inflame, they are subject to inherent deteriorating changes. This has been demonstrated with respect to the secreting cell-particles of the liver, and the elements of the vitreous body of the eye, by the observations of Mr. Bowman; and by the researches of others who have employed the microscope with respect to the elements of brain-substance, muscular fibrillæ, and the secreting cell-particles of the kidneys, &c. &c.

And thus we arrive at the anatomical basis of the distinctions recognised in practical medicine and pathology between *organic* or *specific* and *inflammatory* diseases: that is to say, between degeneration or disease of the special elements of an organ, and the changes, interpolations, and intrusions, incidental to the properties of blood and fibrous tissue—phenomena of inflammation.

It is no part of our present purpose to touch upon the subject of organic or specific diseases further than may be necessary to render intelligible the facts connected with inflammation.

In every organ within microscopic areas, there are elements of the common and of the specific.—The elements of the common are blood, blood-vessels, and fibrous tissue; the elements of the specific is the matter of the specific function: therefore there are in every organ of the body, and within

microscopic areas, elements of two kinds of hypertrophy, atrophy, degeneration, and disease—inflammatory and specific. But such is the minute or microscopic scale upon which the different elements of the living structure commingle and incorporate, that before disease can become an object of practical interest disturbed expressions from the *super-added* become mingled with and complicate the *fundamental*: and thus the function of the parenchyma gives complexion to the symptoms of inflammation. For the illustration of these doctrines we go not to the transcendental, but to the practical.

There are assemblages of symptoms in the living, and results to be seen without microscopic aid, in the dead body, which conclusively establish the fact of their being distinguishable diseases, in which the deviation from the standard of health and healthy structure begins in the elements, and progresses from group to group of the parenchyma, the general fibrous basis and the blood-vessels remaining comparatively but little affected, or clearly suffering in a secondary manner; and conversely, that there are other diseases,—scrofulous diseases, for example, in which the persistence of granulations, ulceration, and pus discharges, proclaim a persistent retrograde condition of blood-vessels; fibrous textures overrun with cell-growth constituting the definitive feature of the disorder. In the liver, kidney, heart, and brain, where specific elements are very densely congregated, and fibrous textures reduced to their minimum amount, specific diseases eliminate themselves in a recognised manner from phenomena of inflammation; and in the skin and mucous membranes, where groups of particular substances are comparatively widely separated, and fibrous texture largely developed, the distinctions we are enforcing are not the less well marked and distinguished.

§ 4. *In the skin*.—Small-pox, herpes, lepra, &c. are diseases quite distinct from erythema and erysipelas. The morbid action in the former is circumscribed, limited within a sphere around the glandulæ and follicles, or groups of them; in the latter it is diffused, spreading widely in the common fibrous basis. Evidence to the same effect—and, moreover, we would impress upon the reader, establishing the specific action of poisonous substances—is furnished upon

the application of irritants to the skin. Blisters excite inflammation in the fibrous basis. Croton oil produces a more pimply redness—an eruption: and antimonial ointment causes pustules to arise resembling those of small-pox. In all these instances there is inflammation, a deteriorating change in the coats of the blood-vessels. But in the one class of diseases this is circumscribed about the groups of the particular substances; in the other it spreads widely in the fibrous basis or areolar tissue, irrespective of glandulæ and follicles. In the former examples inflammation wears the aspect of the *superadded*; in the latter, of the *fundamental*.

§ 5. *In the mucous membranes*.—The mucous membranes, composed of a common fibrous basis, and groups of villi, papillæ, glandulæ, and follicles, are analogous to the skin, and are therefore obnoxious, *in virtue of the common*, (bloodvessels and fibrous textures), to congestion, effusion, hyperæmia, anæmia, and all the phases of inflammatory action; and *in virtue of the special*, to specific hypertrophy, wasting, degeneracy, and disease, to pimply eruptions, acuminated pustules, and specific ulcerations. Amongst the diseases of the mucous membranes, Billard distinguishes in infancy the *follicular* from the *erythematic*: and Rokitsky distinguishes in the adult those of the mucous surface from those of the sub-mucous fibrous basis, gelatinous softening of the stomach, and what he denominates the *typhous process*, from inflammation.

"If we consider," says the latter distinguished pathologist, "that gelatinous softening in none of its stages presents, either at the point of softening or in its vicinity, either hyperæmia, injection, or reddening, and that we are still less able to demonstrate upon the inner surface of the stomach, or in the tissue of its coats, the products of inflammation, we are constrained to infer the non-inflammatory nature of the affection." "This conclusion," he says, "gives a key to the various kinds of softening that occur at advanced periods of life under similar circumstances,—viz. in cerebral affections.*"

To follow out physiologically and pathologically the analysis here indicated with respect to the common and

the special in all the organs of the body, microscopic and large, would be, indeed, to enter upon a wide field of anatomical research: enough has been said to indicate the principle, and to eliminate the fibrous textures as the seat of inflammation, repair, and scrofulous disease.

§ 6. *Of repair, and the imperfections or limitations of cure*.—The characteristic pittings of small-pox, and the analogous marks which may be found remaining after a severe application of antimonial ointment to the skin, not only point out upon what texture the morbid action has been concentrated, but they indicate—as do the scars and seams of a burn—that the parenchyma of the glandulæ is not restored or reconstructed by the process of repair, which fills the void, not by restoring the destroyed or lost form, but with simple fibrous tissue. Pathological anatomy has long demonstrated analogous facts in the mucous membranes: and it appears from our observations in these and other examples of repair or cure, where an original or germ-form has been destroyed, that, with the original form and substance, *the principle* governing the natural distribution of the blood-vessels has also departed; for the arrangement or disposition of these in a scar or a cicatrix, in granulations and lymph, appears to us never to be the same as it was in the unimpaired original growth. Such being the facts, we have, in these instances at least, no evidence of a repetition or revival of the "germ force." On the contrary, we see only effects arising from those qualities of blood which, wherever blood extends, originate a limiting or bounding texture, a correlative of blood, the first phase of which is *corpuscular*, and the concluded form *fibrous*. These imperfections or limitations of cure in the skin may be of little consequence to the welfare of the person; but in mucous membranes and internal organs they become of much more importance: and allied to these in their consequences upon the general or constitutional health are the unnatural fibrous adhesions which very frequently attend the cure of severe inflammation on the free surfaces of fibrous membranes. But we have elsewhere spoken at length upon this part of our subject,* and are therefore content with the following summary:—

* Pathological Anatomy: Sydenham Society's edition, vol. ii. p. 33.

* Healthy and Diseased structure, part ii. ch. 2.

The first phenomenon of repair is inflammation, cells and cell-growth interposing fibrous texture. The second phenomenon of repair is the cure of inflammation; natural fibrous forms abolish and exclude the cell-growth period. But there is often a pause between these two periods. Inflammation subsides, but cure does not advance: unnatural cell-growths maintain their footing, but they do not spread. This is *scrofulous disease*,—a persistent form of retrograde metamorphosis.

Finally, the human body, regarded *analytically*, is composed of three great systems of organs—sentient, motor, and secreting—nourished by the circulation of the blood, and sustained by the coherency of textures, correlatives of blood. In this point of view we have sought to determine the seat of inflammation, and to extricate its definitive phenomena from their complications with the elements and physiology of the parenchymatous substances. Desirable as this is on many grounds, particularly as in interpreting pathological appearances, we must remember that analytical views are unsatisfactory in the practical treatment of disease; because, in the first place, such is the minuteness of the scale upon which different physiological substances commingle and are co-ordinated, that there are everywhere in the living structure, and *within microscopic areas*, elements of the common and of the specific: so that if disease fundamentally begin in the one, it affects the other before it can become an object of practical interest or regard: and in the second place, *synthetically* viewed, all the various elements of the living body are so mutually incorporated and interdependent, that the whole of them form but one person. Look at the relations between *sentient* and *motor* elements. Muscles act instantaneously upon the dictates of the will; but disturb sentient matter, and muscles are divorced from the dominion of the will: they remain quiescent, and waste away. Are not muscles, then, exquisitely sensitive? *Sentient* and *motor* elements are both incorporated with the simple fibres of the *fibrous tissues*, and immediately feel the influence of the first inroads of inflammation. In the deep interior of the brain *sentient elements* are brought into such close and mysterious relations with the *elements of blood*, that the ordinary nature and character of the limiting tissue

of the blood is dispensed with, a kind of embryonic type of circulation here prevailing. Blood and medullary matter seem in this instance to have nothing interposed between them. In the *secreting organs*, and *within microscopic areas*, multitudes of the *secreting cell-particles* are attached to the *containing texture of the blood*: and in the liver the same continuous relations are thought by the best anatomists to prevail between the *secreting elements* and the *venous blood*, as appear to exist in the brain between *sentient elements* and *arterial blood*. It is these synthetical relations which prove to us how dependent every part of the body is upon the circulation of blood, and deprive analytical investigations of the extensive influence which otherwise they must have had upon the art of therapeutics. In the embryo, *germ-masses* or groups of sentient, motor, and secreting elements are founded prior to the flowing of the blood current, but the growth of blood vessels of fibrous textures and bones, upon which the relations of forms and functions depend, is posterior to the circulation; and the healthy constitution of these textures hinges upon a normal metamorphosis of the elements of blood. Such being the facts, what, then, replenishes and maintains the circulating fluid?

In answering this question, we enter upon another and a widely different sphere.

Food, drink, and air, incorporate with blood. Here we pass from the department of the living body to the world of external Nature; and it is to be observed, that the elements of the one cannot be said to be *more necessary* to the *phenomena* of life and health than are those of the other; for the body dies as soon deprived of air as it does deprived of blood.

78, Wimpole Street, July 20, 1850.

VESICULAR DISEASE IN A NEW-BORN INFANT.

THE disease appeared on the second or third day, and lasted about a week. Upon the upper extremities the vesicles were quite numerous, and about as large as the head of a pin; but upon the abdomen, where there were only a few, they were probably from four to six lines in diameter. There was little or no redness about them, and they at last dried up.—*American Journal of Medical Sciences* for July, 1850.

AN ESSAY ON
UNHEALTHY INFLAMMATIONS.

By M. BROKE GALLWEY, Esq.
Assistant-Surgeon Royal Regiment of Artillery,
Woolwich, Kent.

[Continued from p. 411.]

ERYSIPELAS (continued).

A true blood poison disease—Physical peculiarities of the blood—the clot—the serum—Clinical peculiarities—Excess of fibrin in all the phlegmasiæ—In erysipelas—No measure or proof of sthenic action—Proximate cause of the disease—Opinions of the older writers thereon.

But if we turn to the *humoral* aspect of the disease, a far more satisfactory escape from these perplexities will be found, if I mistake not, to await our inquiries; and under this conviction I shall now devote some space to a consideration of the fluids in erysipelas.

Physical characters of the blood in erysipelas.—The blood of an erysipelatous patient, after standing for a while, undergoes the usual separation into serum and crassamentum. But different writers have given different descriptions of the physical appearances of each of these; the clot by some being characterized as loose and large; by others, the reverse of these. This discrepancy would seem to arise from the probability of the blood so examined having been derived from different forms of the disease; for, where the areolar tissue has become involved, and febrile action runs high, the clot, *a priori*, might be expected to be more consistent than in another case where the cutis only was affected, and little constitutional disturbance present. The serum, on the other hand, seems almost by common consent to possess unusual qualities, being described by writers in general as thin, acrid, less glutinous than it should be, and remarkable for its deep yellow dye; or, as some say, for its mixture of yellow and green. Bursarius speaks of the blood as “*rutilans, spumidus, vis coherens*” (Inst. Med. Pract. vol. ii. p. 22). Sennertus as “*tenuior et calidior*” than in phlegmon (De Fabr. lib. ii. c. 16), &c. &c. But, not having the blood of any erysipelatous subject on my own hands, or on my conscience either, I cannot speak from my personal know-

ledge of its state during life. After death, it is in general found to be darker than in those who have died of healthy forms of inflammation, and likewise *semi-fluid*, having from this latter quality escaped into the areolar tissue and cavities of certain organs.

Constitution of the blood in erysipelas.

—Almost all observers who have analysed the blood in this disease are agreed as to an *excess of fibrin* being a prominent feature in its chemical history. Bearing in mind that in healthy blood the mean amount of fibrin is about 2·2* in 1000 parts, the following statement will show a notable increase in its proportion in erysipelatous affections. “Andral and Gavarret have made eight analyses of the blood of five persons, four of whom were suffering from erysipelas of the face, and one from inflammatory erysipelas of the foot. In seven of these cases the fibrin was materially increased; in three instances it amounted to 5·0; in three to 6·0; and in one to 7·0; in a much shorter and milder case, in which there was but little fever, it amounted to only 3·8.”†

Rindskopf, in a case of erysipelas of the hand, found the fibrin increased to as high a point as 7·71‡ in 1000 parts. Heller, in a case of erysipelas of the face, estimated it at 5·45.§

Simon has not analysed the blood himself in erysipelas. Garrod merely repeats the asserted fact, on Andral’s and Gavarret’s testimony, that the amount of fibrin “is very great:” and Thompson only incidentally does the same.||

Andral and Gavarret found a notable diminution in the amount of red globules; and this conclusion would appear to confirm the opinion of Simon, that in proportion to the augmentation of the fibrin is the diminution in the amount of red globules; for he lays it down that the fibrin is derived directly from the constituent elements of the blood-globules,—an opinion to which the former chemists do not assent, who rather maintain that the hæmatoglobulin

* Lectures on the Chemistry of Pathology and Therapeutics, by Alfred B. Garrod, M.D.; Lancet for 1848, vol. ii. p. 86. Lecanu estimates it at something higher than 3; and Christison at 3.

† Animal Chemistry with reference to the Physiology and Pathology of Man, by Dr. J. Franz Simon, vol. i. p. 270.

|| Chemistry of Animal Bodies, by Thomas Thomson, M.D., p. 374.

is increased in plethoric conditions of the system.*

In the present unsatisfactory state of our knowledge in relation to the diseased conditions of the blood, I do not think it would be for the interests of my present subject to enter more minutely into the analysis of this fluid in erysipelas; for although we might attain to the knowledge of several individual facts in relation to its other constituents, we know so little at present of the *true interpretation* intended by nature to be placed upon the changes which they undergo in disease, that such inquiry would almost necessarily precipitate me into speculations, and lead us away from the high road of our subject.

"Amicos Cicero, amicus Plato, sed magis amicus Veritas."

Let us confine ourselves, then, to a few observations upon the most remarkable and interesting peculiarity which meets us at the outset in our examination of the animal chemistry of erysipelas,—to wit, the *notable augmentation in the amount of fibrin* which the blood in this disease discloses.

The occurrence of an increase in the amount of fibrin in disease appears, by the common consent of all inquirers at the present day, to be conclusive as to the existence of a state of *hypermosis*, or of an inflammatory condition, in whatsoever circumstances of the system the blood betrays such alteration. "The development of an inflammatory disorder," observe Becquerel and Rodier, "produces remarkable modifications in the composition of the blood, of which the most striking is the increase of fibrin." Simon is equally explicit upon the point. "We find accompanying these physical symptoms" (alluding to the density of the clot) "an excess of fibrin and a diminution of hæmatoglobulin, as well as of the solid constituents of the blood generally; and in proportion to the degree in which these phenomena are observed, we may infer a greater or less amount of inflammatory action."

The direct connection, then, between

* Simon believes that the opposite opinions on this subject between the French chemical physiologists and himself may be traced to the different methods of analysis adopted by them respectively. Nasse has also found that the corpuscles and fibrin are generally in an inverse ratio; and Becquerel and Rodier's experiments show the same in their analysis of blood in a number of cases of well-marked inflammation.

an excess of fibrin in the blood and a state of inflammation, appears to have become a necessary and fundamental canon of our faith—a "golden image" of truth "set up" by the Nebuchadnezzars of our art, before which we are commanded to bow!

But, though indicative of a *certain condition of sanguification*, the important practical question to be solved in connection with its occurrence is, whether this excess of fibrin can be looked upon as a measure of *power* in the system at the time? For, it is the very essence of that truth (if it be a truth) which I am labouring to establish, that one inflammation may be associated with strength, and another with the opposite condition. In these opposite forms of inflammation, however, it seems to be clearly established that an excess of fibrin is equally characteristic of each. It is in marked excess in *phthisis*, as well as in some other diseases of a still more decidedly asthenic nature.

And now for a *fact or two* in connection with the circumstances under which the fibrin discloses itself in excess; for facts, like figures, constitute a stubborn sort of arithmetic.

Chlorosis.—Becquerel and Rodier have furnished a table showing the mean composition of the several constituents of the blood in six chlorotic girls. That of the fibrin they found to be 3.4.

"Andral and Gavarret have made twelve analyses of the blood of nine cases of confirmed chlorosis. In their cases the maximum amount of fibrin was 3.6; the minimum 2.1; the mean 2.9.

"Golding Bird states that the blood in chlorosis forms *just as solid a clot as in inflammatory diseases*: and Jennings (*Lancet*, 1840, p. 887) observed even a *buffy coat* on the clot of chlorotic persons in the absence of all inflammatory symptoms."* Andral and Gavarret have also constantly observed the buffy coat in chlorotic blood. Simon admits that the quantity of fibrin in chlorosis "is normal, or only slightly diminished;" whilst most of the French and German writers declare that it is *in excess*.

With the great diminution in the amount of hæmatoglobulin, and with the excess of water in the blood of chlo-

* Simon's Chemistry.

rotic subjects, I have nothing to do in the present consideration of its constitution. That which now concerns us alone is the fact, that in a disease the nature of which is so much the opposite to that of inflammation that death every now and then overtakes the subject of it from no other apparent cause than a cessation of the heart's action for *lack of the power to go on*, that constituent of the blood which is believed to endow it with the quality of *strength* is generally present in excess. In a word, that the blood in chlorosis is distinguished by a feature, the presence of which in disease is the acknowledged symbol of inflammation,—viz. an excess of fibrin.

Scorbutus.—Dr. Garrod has examined the blood in this disease, and “sometimes found a buffed and cupped state of clot; sometimes a normal clot; but never a dissolved state of the fluid.”* He quotes the results of Mr. Busk's experiments upon scorbutic blood in three cases of the disease, in all of which the amount of fibrin was in excess.† In the first its amount was 6·5; in the second 4·5; and in the third 5·9: and yet scorbutus is a disease in which the vis vitæ is, by general consent, regarded as being below par.

Acute diseases.—In some of the phlegmasiæ an excess of fibrin will be found in the blood after the patient has been almost blooded to the edge of his grave! Thus, in an analysis of the blood of a rheumatic patient by MM. Andral and Gavarret, who “had been bled six times, besides having had 200 leeches applied,” the fibrin was still found in *considerable excess*—i. e. at 4·6!‡

We know this to be a common circumstance in rheumatism—a pre-eminently “*unhealthy*” form of inflammation, as I shall probably endeavour to prove by and by.

Andral and Gavarret, again, have given the analysis of the blood in three cases of pneumonia, in the first and second of which four blood-lettings were practised, and three in the last. It will be interesting to tabulate the changes in the amount of fibrin which were consequent in each of these cases upon the depletion.

	Venesection.	Fibrin.
1st Case	1.	4·0
	2.	5·5
	3.	6·5
	4.	9·0 (?)
2d Case	1.	5·2
	2.	7·3
	3.	6·9
	4.	8·0 (?)
3d Case	1.	5·5
	2.	6·8
	3.	6·4

Mons. Simon (from whose work the foregoing sketch is derived) endeavours, it is true, to explain away this very striking disclosure. “If the bleedings,” says he, “are carried beyond a certain extent, the fibrin as well as the corpuscles are diminished.” But having the clearest evidence that after the *fourth* abstraction of blood the amount of fibrin is in notable excess, and that each depletion augmented its proportion, I think I might be almost justified in the suggestion, whether the diminution in the amount of fibrin in subsequent bleedings—that is, when “carried beyond a certain extent,” as declared by Simon to be the case—might not be satisfactorily accounted for upon the supposition that the fibrin is only diminished from the circumstance of there being *no blood left to furnish it?*

Mons. Andral has some observations upon the various circumstances under which fibrin is found in the blood as well in excess as below the healthy mark, which are so interesting and pertinent to my present subject, that I think I need offer no apology for inserting them here at length.

“The fibrine may be altered either in quantity or in quality. In the first place, there are cases in which this principle is more abundant than usual, or at least in greater proportion relatively to the water and albumen. In such cases, the blood, when drawn from a vein, forms in the vessel that receives it a clot with little or no serum. These are, however, to be *divided into two classes*. In the first class of cases the fibrin constituting the clot still contains a pretty large quantity of serum, which may be separated from it by pressure: in these the coagulum has but little density. In the second, on the contrary, the clot is very dense, and a little fluid albumen can, with difficulty, be squeezed out of it. In the first class;

* On the “Chemistry of Pathology and Therapeutics,” Lancet, 1848, vol. ii. p. 142.

† Mr. Busk has also found the blood in some of his cases both buffed and cupped.

‡ Simon, vol. iii. p. 277.

the relative increase of quantity of the fibrine is only apparent; in the second, it is real. We must take care not to confound them, as they belong to different states of the system. The very fibrinous blood is commonly called *rich blood*: it may either depend simply on a vigorous constitution, or on certain morbid states.

"We learn, then, from observation, that in the same quantity of blood the fibrine may exist in various proportions, being sometimes above and sometimes below the regular complement; how this fibrine is itself composed of determinate quantities of oxygen, hydrogen, azote, and carbon; and, if these elements are derived from the air and food, and are found in more or less considerable proportions in the different excretions, it is natural to suppose that they may also exist in variable proportions in the fibrine, and thus modify its nature: and, indeed, it is possible that their relative excess or deficiency may have some influence in the production of certain morbid states.

"The force that tends to keep the globules of fibrine at a certain distance from each other during life, may be so modified as that they shall have a tendency to run together, as they naturally do after death; and hence may result the spontaneous coagulation of the blood in its vessels during life.

"We have just been considering the cases in which there is a real augmentation of the force of aggregation that keeps together the particles of the fibrine of the blood. In other cases there is, on the contrary, a diminution of this force; and the result is, either a less tendency in the blood to coagulate, or a total absence of coagulum. When there is one, it is remarkably soft, offers scarcely any resistance to the finger, and is converted by a slight agitation into a reddish fluid. In other cases there is no coagulum, and we find the fibrine broken up into small fragments, that remain suspended in the serum, or fall to the bottom of the vessel. Lastly, in other cases there is not any appearance even of these fibrinous particles, but the fibrine is completely mixed with the serum, producing a fluid mass of a reddish or blackish colour. These different appearances presented by the blood when drawn from a vein, may be observed also in the vessels in the dead body: these are sometimes

filled with coagulated blood of greater or less consistence; while on other occasions there is nothing to be found in the heart, arteries, or veins, but a perfectly fluid blood, resembling water charged with a red, brown, or black colouring matter. In such cases it has been ascertained by chemical analysis that *the fibrine is not absent*, but that it is altered in its nature, so as to be no longer spontaneously coagulable. In some few cases I have seen the fibrine assuming still another appearance: instead of a coagulum, there was at the bottom of the vessel a homogeneous stratum, sometimes of a deep brown, and sometimes of a dirty grey, resembling bad pus more than blood."*

In these most interesting observations we discover an explanation of that apparent contradiction in the behaviour of fibrine in diseased states of the blood, which consists in the fact that, while we acknowledge the firmness or looseness of the clot to be dependent upon the greater or less amount of fibrine in the same, that constituent of the vital fluid may still, by analysis, give evidence of its presence in excess, under circumstances in which its entire absence might, *a priori*, have been looked for. The fact that fibrine may part with that property which is thought to be almost distinctive of its existence—namely, its *tendency to coagulate*, is, as far as I know, a new and highly important feature in its history, and one a consideration of which tends to clear up much of the difficulty and obscurity to which I have just adverted,—its actual presence, as shown by analysis, where a *dissolved* state of the humors appears to be a prominent condition.†

It may not be out of place here, per-

* Pathological Anatomy, vol. i., pp. 645-9.

† In his second Lecture on Inflammation, Mr. Paget records the following case, which has an interesting relation to the present subject:—"A man received a compound fracture of the leg, and it was followed by phlegmonous inflammation and abscesses up the limb. As soon as the inflammation had subsided enough, the limb was amputated; and three days afterwards, in examining it, a quantity of serous-looking fluid oozed from the cut through the integument. I collected some of this, and it formed a perfect fibrinous clot; yet the fibrine in this case had remained among the tissues *without coagulating* for three days after the death of the limb, and for many more days during the life of the patient." "One can rarely tell (adds Mr. Paget) why the coagulation of the fibrine in these cases should be delayed. There are here the same difficulties as are in all the exceptions from the general rules of the coagulation of the blood."—MEDICAL GAZETTE, June 14, 1850, pp. 1010-11.

haps, to advert briefly to M. Simon's views of the rationale of the changes superinduced by inflammation in the constituents of the blood.

"Numerous observations" (he observes) "have shown us that blood retained for any length of time in an organ, and thus prevented from meeting with a due supply of oxygen, becomes poorer instead of richer in fibrine; whereas, there is undoubted evidence that in inflammation the fibrine is increased." M. Simon believes that as, in inflammatory conditions of the system, a more rapid circulation of the blood is induced "through the lungs, and other organs that exert a modifying influence on its composition," the blood in consequence gives off a larger amount of carbonic acid than in the normal condition, and imbibes an extraordinary quantum of oxygen; and that, on this account, the development of the blood-corpuscles will be hastened, their vitality heightened, and more corpuscles be consumed than in the normal state; bearing always in mind that M. Simon supposes the fibrine to be directly formed from the blood-corpuscles.

"Hence" (he says) "if we only assume that the circulation is increased by the reaction of the organism in inflammatory affections, an explanation is at once afforded us of the change that occurs in the composition of the blood in hyperionosis, and, at the same time, of its heightened temperature" (vol. i., p. 286).

In brief, that the greater the frequency with which the blood performs its revolution through the lungs, and is submitted to fresh collision with atmospheric air, the greater is the manufacture and subsequent metamorphosis of blood-globules into fibrine. Simon admits that the increased velocity of the circulation cannot be assumed to be the *sole* cause of the change in the blood; by which admission he anticipates the objection to which he would otherwise have exposed his hypothesis—to wit, that in typhus fever, and many other diseases of prostration, there is a great increase in the rapidity of the blood's transit through the lungs, where the fibrine is notably deficient in that fluid.

Reviewing the several conflicting circumstances in connection with the excess or deficiency of fibrine in the blood which I have now imperfectly brought under

review, I think I am warranted in deducing from them the following conclusions:—

1st, That although an excess of fibrine in the blood does appear to be a *constant* accompaniment of inflammation, it is not infrequently met with also in *opposite* conditions of sanguification; whilst its amount is further influenced in some cases by the extent of the orifice through which the blood flows, and by the form of the vessel which receives it.

2ndly, That in the inflammations, strictly so-called, it is a common occurrence to find its amount increased in proportion as we reduce the entire mass of the blood by venesection; wherefrom it would seem that it is not upon a plethoric condition of the individual that its excess, even in these cases, depends.

3dly, That there is absolute proof, in the foregoing circumstances, that its excess in the blood is *not a measure of the amount of power in the system* and, consequently, not a warranty for depletion or for depression.

4thly and lastly, That we know very little either of its natural or morbid history beyond the fact, that its excess or deficiency "*occurs by the will of God*,"* and does not justify us, in the present state of our knowledge, in putting our own interpretation upon its meaning.†

If, in the foregoing analysis of the *actual amount* of information which we possess, as derived from a consideration of the chemical peculiarities of the blood in disease, I shall appear to be setting up the thoughts of a very humble and insignificant pretender in array against those of established authority, and to be seeking to loosen the foundations of those structures which better men have erected as beacons for the ordinary traveller; if I should seem to figure in such light in the eyes of the "master builders of the

* Avicenna.

† "In estimating the quantity of fibrine, chemists have not taken account of the *white* corpuscles of the blood. These cannot, by any mode of analysis yet invented, be separated from the fibrine of mammalian blood; their composition is unknown, but their weight is always included in the estimate of the fibrine. In health, they may, perhaps, add too little to its weight to merit consideration; but in many diseases, especially in inflammatory and other blood diseases, in which the fibrin is said to be increased, these corpuscles become so numerous, that a large proportion of the supposed increase of fibrine must be due to their being weighed with it. On this account all the statements respecting the increase of fibrine in certain diseases need revision."—Kirke's Handbook of Physiology, p. 66.

commonwealth of learning," my exculpation of myself and of my misdeeds must be—

That "I pretend not to publish this essay for the information of men of large thoughts and quick apprehensions. To such masters of knowledge I profess myself a scholar, and therefore warn them beforehand not to suspect anything here but what, being spun out of my own coarse thoughts, is fitted to men of my own size; to whom, perhaps, it will not be unacceptable that I have taken some pains to make plain and familiar to their thoughts some truths which *established prejudice*, or the abstractedness of the ideas themselves, might render difficult. The imputation of novelty is a terrible charge among men who judge of men's heads as they do of their perukes,—by the fashion, and can allow none to be right but the received doctrine." But "he who has raised himself above the *alms-basket*, and, not content to live lazily on scraps of begged opinions, sets his own thoughts on work to find and follow truth, will (whatever he lights on) not miss the hunter's satisfaction; every moment of his pursuit will reward his pains with some delight; and he will have reason to think his time not ill-spent, even when he cannot much boast of any great acquisition."*

Having thus endeavoured to make apparent what this disease is *not*, let us lose no further time in examining into the vexed question of what it is.

I have expended some ink-shed in an endeavour to show that its simple phlogistic nature was not established by the coexistence of an excess of fibrine in the blood; whilst the several peculiarities in its natural history, to which I have briefly also adverted, suffice to point out its *distant relationship only* to the family of the true phlegmasiæ.

In tracing the literary history of erysipelas (vide *Lancet*, Dec. 22, 1849), I dwell upon the interesting fact, that from the earliest periods of medicine this disorder had been regarded by the observant ancients as an *unhealthy form of inflammation*, and not the *product of pure blood*. Thus Galen laid it down that it has its origin in a "*bilious humour*;"† and such strong hold did this

belief take of the minds of his successors, that it has been handed down very nearly to our own day as an established fact in the pathology of the disease. Whilst Paulus Ægineta significantly distinguishes a phlegmon from erysipelas as a disease in which "*good blood* of moderate consistence rushes abundantly to a part," &c., the latter (erysipelas) being known "by the symptoms of very acrid bile putrified along with a deficient blood," Burserius, who has left us an excellent history of erysipelas, attributes its cause to "humor quidam tenuis, calidus, acerque, *biliosæ sanguinis* parti a veteribus dictæ quam similissimus, intus utcumque genitus, et primum nervosum genus, deinde cor, arteriasque repente percollens, a reliquis paulatim liquoribus, motu febrili oborto, secedens, atque ad cutim alicubi propulsus, aut in ea primario etiam defixus, et locum in quo sistitur, vel latebat, *peculiariter* irritans atque inflammandum."*

Hoffmann was convinced that erysipelas has its origin in some acrid poison: but, while in one place he tells us that that poison is "not of a bilious or saline, but rather of a caustic and acrid nature," he immediately afterwards declares it as his opinion that it springs from "*bile in a state of corruption*, to the degeneration of which many causes have contributed."‡

Some colouring might be given to this time-honoured doctrine by a reference to the most recent researches into the mutual action of bile and blood upon each other. I have stated that Andral and Gavarret found a marked diminution in the amount of red globules in erysipematous blood. Now, according to Hunefeld, and to Simon (who confirms the observations of the first), "on the addition of fresh bile the blood immediately becomes clear, and the *corpuscles disappear*."†

Simon experimented upon the blood with pure bilin, which "produces the instantaneous solution of the corpuscles." Some uncertainty, however, still

cap. 1).—"Si ex sanguine et flava bile" (the reader is aware that the ancients attached great importance to the distinction between yellow and black bile) "justo calidioribus fluxio mista fuerit, aut ex sanguine, quidem, sed fervido et substantia tenuissimo" (or even from hot blood alone much attenuated), "erysipelas vocatur ille affectus."

† Febris Erysipelacea.

‡ Simon's Chemistry, vol. i. p. 110-111.

* Locke.

† Galen does not appear to have thought the presence of bile in the blood always necessary to the production of erysipelas; for he says in one of his works (Meth. Med. ad Glaucum, lib. II.

prevails amongst even the highest order of animal chemists as to the effects of the constituents of bile upon the circulatory mass; whilst certain of them are even of opinion that they have never been discovered in the blood at all. Becquerel and Rodier found the serum, in cases of icterus, always tinged with bile pigment: and Tiedemann and Gmelin have drawn the same conclusions from their analysis of the serum of icteric blood, whilst the clot has been of the colour of healthy blood.

Schönbein has found the serum in erysipelas to be invariably tinged yellow with the colouring matter of the bile. But then a bright yellow colour distinguishes the serum also in several other diseases. Such is generally the case in phthisis.* Van Swieten has the following not impertinent remark upon this conceit of the ancients. "As the part invaded with an erysipelas appeared of a yellowish-red colour, therefore the ancient physicians accused the bile as the principal cause; but we at present know that the serum of the blood is naturally yellow; so that if a little cruor stagnates with much serum in the pellucid vessels which are obstructed and inflamed, the affected part will then appear of a reddish-yellow colour."†

"An erysipelas," says Wiseman, "is generated of a hot serum in the blood, and affects the superficies of the skin with a shining, pale, red, or citron colour." "This serum, according to its several degrees of recess from its natural state towards that of cholera, doth produce several diseases. When the recess is less, and the sharpness of it but little, then it doth only cause a reddish blush upon the skin, from which the name of erysipelas is, or at least may be, derived." "That which I propose to treat of is the erysipelas à sanguine bilioso from choleric blood, which affects only the outward parts, none of which escape its tenuity and subtileness." Again, "The matter of this erysipelas is already described to be a thin choleric humour; the fountain of it is the blood, which, by its capillary arteries, dischargeth it upon that part" (the skin) "as often as in

bilious or malignant and pestilential fevers it is provoked thereunto," &c.*

Desault, among the moderns, has inclined somewhat towards the opinion, that at least one form of erysipelas was occasioned by, or associated with, the circulation of bile in the capillaries of the skin. His division of the disease is into phlegmonous, *bilious*, and local. This old doctrine of the congestion of the bile has also been in some measure revived by Tissot, who attributes the cause of erysipelas to a bilious humor diffused through the mass of the blood.†

"The erysipelas," says an old English surgeon, "is often attended with violent itching, the consequence of miliary particles obstructing the cutaneous vessels, and always with some degree of fever. How far," he continues, "the redundancy of bile in the blood during this state of inflammation in any part may confine it to the skin, I will not attempt to determine; but, though the blood, on pressure with the fingers in the inflamed part, immediately retires, and soon returns, nevertheless in that short interval we observe the skin has not its usual whiteness, and the vesicles that attend this disease are always full of a *yellowish serum*."‡

Sauvages considers Sennertus a sufficiently good authority upon the strictly humoral nature of the disease to quote his opinion when classifying the varieties of erysipelas. "Erysipelas juxta Sennertum definitur febris continua a sanguinis parte *tensiore corrupta* et inflammata, quâ ut natura se liberet, eam in aliquam partem externam expellit formâ tumoris aut maculæ rubræ, latæ, quæ à parte in partem serpit."§

Thus we observe from how early a period in the history of medicine, and how continuously down to the present day, the disease which we are considering has been attributed by physicians to the circulation of some impure material in the blood;|| and that this is the origo mali in every form which erysipelas observes (the morbid material or poison being the true agent in the causation of

* Wiseman's *Chirurgical Treatises*, vol. i. p. 55-7.

† Tissot, *Avant un Peuple*.

§ Sauvages, p. 446.

|| Van Helmont had a whimsical notion that erysipelas was "apostema maxime igneum, in quo ascendunt spiritus vitales et canit mercurius lacessitus, et valuti in iram provocantur."

* John Hunter observed that the serum of the blood undergoes this change of colour where rhubarb has been taken for any time (vol. iii. p. 63).

† Van Swieten's *Commentaries*, vol. iii. p. 330-1.

its peculiarities) I think so self-evident, that I would lay it down as a canon in our creed.

It is true we are as far at the present day from resolving the real nature of this poison as was Galen himself, who, however, as I have shown, partook of none of our modern doubts and diffidence upon the point. It is to be feared, however, that the present is one of those many instances in which, to use a significant remark of Voltaire's, we are not likely to be permitted "to peep into the bottom of nature's basket." A French writer has well observed (speaking of this disease), "On a beaucoup disserté sur la cause *prochaine* de cette maladie; mais on n'a guère réussi qu'à nous donner des idées vagues ou erronnées, plus propres à embrouiller la matière qu'à l'éclaircir, comme il arrive toujours lorsqu'on veut expliquer ce qui est *inexplicable*."*

[To be continued.]

THE HARDSHIPS OF YOUNG PHYSICIANS.

It has become a proverb, not only in the profession but out of it, that it requires from five to ten years' starvation before the young physician can support himself upon his collected receipts. He may possess all the qualifications requisite to constitute a good physician; he may have rendered excellent service in cases where he has attended; but he cannot be appreciated and patronised, for he is a young man, *inexperienced* in the mysteries of a sick chamber, —and therefore cannot cure disease. How is experience in such a case to be obtained? for the people upon whom he relies for support will not give it until he has had a certain *number of years' practice*. This practice, if obtained at all, is of that peculiar kind which may perhaps benefit his patient, but "enriches not him." He waits upon the poor, whose compensative means are very limited, although at times he receives from them that which is priceless — a heartfelt gratitude and the invoking of heaven's blessings. The better or richer class seldom employ the young physician unless compelled to by accidental circumstances. Their creed is: if we *pay*, we will have what is considered best, —though it is allowable that they are often incompetent to decide upon the question of qualifications. A physician who can repeat every word he has read on medical subjects, and

be able to tell you the number of fibrils in any given muscle, may yet be unable to distinguish one disease from another, or decide upon a proper course of treatment. This same class of patients, who never employ the young physician because they have no confidence in him, do not hesitate, in numberless instances, to purchase secret nostrums, or even to employ the parties who prepare them. If any new *pathy* should be introduced among the people, it only requires its founder to demonstrate its wonderful principles, and promise *impossibilities*, in order to succeed in obtaining advocates and plenty of patronage. The self-vaunted quack gets a large harvest, and that, too, from only a six months' or year's practice. Every one has confidence in him, to be sure, for he *promises* so much, and can tell exactly what *ails* a person at the first glance. Perhaps this wonderful doctor has often to go miles to see a patient; or, may be, his fame is such, that the halt, the lame, and blind come from afar to him to be cured.

In the practice of medicine it would appear, then, that it requires a certain amount of egotism to succeed well. It is one of the weaknesses of our nature to believe in impossibilities; and the more our credulity is imposed upon, the more believing and satisfied are we. Now what encouragement can there possibly be for the young educated physician, fresh from his college, although his brow may be covered with laurels of distinction? He has only to look around him to see that it is not always true merit that makes the practitioner! There is Dr. A., who has been in practice some twelve or fifteen years, but cannot with his earnings pay his office dues. Drs. B. and C. are as badly off; while Drs. D. and E., having been in practice about the same time, are taking the better part of the business. The three first-mentioned doctors are known to be men of science and of rare attainments, —even the public themselves are willing to allow that; while the other medical gentlemen are not so well informed, nor in any respect so well qualified for their posts. It does not require much perception, likewise, for him to see that the arrant quack is not only on a par with the educated physician, but in many cases the palm is given to him. It is true, the success of this class is not permanent, as they stay only long enough in one place to fleece the pockets of their victims there. It would be well if the matter ended here; but it does not, —for as soon as one class of quacks lose caste, there are others, more *pretending*, ready to spring up. —*Boston Medical Journal*.

MEDICAL GAZETTE.

FRIDAY, SEPTEMBER 20, 1850.

It is with regret we perceive, from the Third Report of the Convention of Poor-law Medical Officers, that the disinterested efforts of the Committee have not received that co-operation from the Poor-law Staff which they had a right to expect, and which the medical officers of Unions were equitably bound to afford. It seems that in order to improve the position of Union surgeons, and to obtain redress for the grievances under which they are well known to labour, the Committee endeavoured to establish a Poor-law Medical League, with Branch Associations in the principal towns and cities of England and Wales. A circular letter was therefore addressed to each Poor-law medical officer, in order that the opinions of all might be ascertained. Letters were thus sent to 8000 persons, and the number of answers received amounted only to 263,—a number comprising about one-twelfth of the whole number of Union officers! Upon examining the answers, it appeared that there were in favour of the proposed Association, 178; doubtful as to the usefulness or probable success of the plan, 36; refusals to co-operate, or to contribute one shilling monthly, 46. The idea of forming such an Association was therefore abandoned.

An interview with Mr. Baines, the President of the Poor-law Board, led to the usual result of official interviews—i. e. the President had neither the disposition nor intention to interfere for the purpose of procuring a better scale of remuneration with permanency of office. He candidly admitted that the question of finance was the great difficulty. "Throughout the country

the demands upon the rates had lately been increasing. He had no reason to believe that any mode of administering medical relief, except as now through the Boards of Guardians, would be acceptable to the country in general. The plan of placing the entire cost on the Consolidated Fund was one which Sir George Grey *might* deal with."

Foiled in this endeavour to enlist the efficient aid of the President, the Committee addressed themselves to the Colleges of Physicians and Surgeons, as well as to the Apothecaries' Society, in the hope that, as medical corporations, they would be induced to memorialize the Poor-law Board in favour of the three leading points of an amended system of medical relief—namely, *permanency of office, responsibility to medical authority, and payment proportionate to duties performed*. Here, again, the Committee were unsuccessful. The Colleges of Physicians and Surgeons declined any further interference in the matter, and the Society of Apothecaries allowed the subject to drop *sub silentio*.

On this the Committee remark:—

"The Poor-law medical officers will not fail to observe that no disposition is shown by any of the existing medical corporations *strenuously* to labour for the amendment of a system admitted by themselves to be oppressive to at least 8000 of their professional brethren in office, and indirectly to every member of the whole profession.*

The subject of remuneration for extra services during the prevalence of malignant cholera has been on several occasions noticed in our columns. It is creditable to the Committee that they devoted all their energies to procure this act of justice for their professional brethren. It is well known, however, that the divided jurisdictions of the

* The apathy of the Medical Corporations cannot be considered deserving of grave censure, when it appears from the Report that out of 8000 Poor-law Medical Officers, 2,500 have shown no disposition to labour in any way for the amendment of an oppressive system!

Board of Health, the Poor-law Board, and the Rural Boards of Guardians, practically defeated the good intentions of the Legislature on this subject. The following extract from the Report gives a short summary of the results attending this application:—

“It appears that the Poor-law Board had power to regulate the *salaries* of medical officers, and also to enforce the performance of such duties on their part, as the guardians, under recent authority of the Health Board, were obliged to see carried out. At the same time the guardians *would not*, and the Board of Health *could not*, award additional recompense for such additional labours, which were evidently beyond the letter, and even the spirit, of the medical officers' contract. It was obvious that the Poor-law Board rather shunned grappling with the question, as it would place them too often in antagonism with the Boards of Guardians. On the other side, should the management of the medical attendance on the sick poor be transferred to the General Board of Health, there was no evidence that the union medical officers would be benefited.”

The answer of the President of the Poor-law Board was, as usual, marked by official politeness, but left the question of increased remuneration in the hands of those patterns of economy, the Boards of Guardians:—

“He admitted that he had the requisite power which on many occasions had been exercised favourably toward the medical officers; but with respect to cholera, and other epidemics, the Poor-law Board had not the power to lay down any scale of remuneration in anticipation of extraordinary services, but the power of granting reasonable remuneration for the same was vested in the guardians; and that, *whenever* an increase of salary or payment was proposed by them, the Poor-law Board had always much pleasure in confirming the same.”

From another paragraph in the Report, it would also appear that when a *diminution* “of salary or payment was proposed by the guardians, the

Poor-law Board had also much pleasure in confirming the same.”

“After the early and repeated assurances of sympathy, and of a desire to ameliorate the status of the Union surgeons made by the Poor-law Board, the Committee were not prepared to receive an account of the treatment exercised by that Board toward the surgeons of the Holborn Union. In this case, not only has a reduction of salary to so low an amount as eightpence per case been *sanctioned*, but it was actually met by a suggestion from the Poor-law Board for even a *further* diminution of the payment, and an *augmentation* of the work of the medical officers.”

This mode of dealing with the Union medical officers is neither candid nor fair. It clearly shows that, while the reasonable demands of the Committee are met by official promises and formal intimations of sympathy, it is the plain and obvious intention of the Poor-law Board to co-operate with the guardians in all financial matters.

Under the present system, it is well known that the screw has been applied to its maximum extent. The order of the day appears to be, increased work and diminished payments. In illustration of the oppressive and impracticable nature of the duties demanded of the medical officers of the Stepney Union, it is stated in the Report that one of them was actually summoned to attend *six* cases of midwifery requiring *immediate* assistance in distant parts of his district in one day! Rural Boards of Guardians have treated with contempt the consolidated order requiring payment for extras, and have handed over the sick poor to any half-starved adventurer who happened to hold a diploma, and who had no chance of succeeding in any more lucrative branch of practice.

It is a great and glaring fact, and one deserving of the severest reprehension, that while Lord Ebrington, a nobleman with comparative independence, receives

as a Secretary of the Poor-law Board a salary of £1,500 per annum for giving up only a moderate portion of his time to the duties of his office, the Union officers are paid for medicines and medical attendance on each sick pauper a sum which is *less than half the cost* of drugs alone in the ordinary treatment of a hospital patient. How can it be explained that, while the salaries of Union surgeons are thus cut down, a noble secretary of the Board receives, for performing not a hundredth part of the labour, an amount equal to the united salaries of about forty medical officers!

The Committee append the following conclusions to their Report:—

"1st. The *disjointed efforts* made by them with much zeal during the last two years, if continued, cannot do more than keep up a teasing agitation, wasting the time and paining the feelings of the few gentlemen who regularly devote themselves to the work.

"2nd. That there is no reason to think that the Poor-law Board will ever take steps to remedy the hardships of the union surgeons, and to correct the misrule under which they serve and the sick poor suffer, *until they can be forced to such a measure*. A cessation of the present undue professional competition must take place; a loud voice, with a resolute purpose, must be raised in the Commons, and well supported on the hustings in every borough and county. It is not too much to state that the medical profession should be equal, by their numbers as well as by their rightful influence, to accomplish what is equally due to themselves, the sick poor, and the rate-payers.

"3rd. That the attempts now made by the Poor-law Board to engage medical officers without private practice for the service of the poor, could not, without much difficulty, be successfully applied to rural districts. The plan of engaging a class of gentlemen for exclusive attendance on the poor is of such very questionable advantage, that the Poor-law Relief Committee, reporting to the House of Commons in August 1838, said 'They felt it to be most important that the poor should be perfectly satisfied with their medical attendants; and with this view it appears to be desirable, as,

indeed, is almost always the case, that the *care of the poor should be confided to the same person who is in the habit of visiting their richer neighbours*.' Such an arrangement as that attempted to be carried out by the Poor-law Board will only work well for the public, or for the profession, when the duties of union surgeons shall be blended with those of Officers of Health, under the control of the General Board of Health, or some other authority independent of the Guardians and Poor-law Board, and adequately paid for by the State.

"4th. That as the public are more convinced than formerly of the false position in which the union surgeon is placed, they will be satisfied that it is their duty to provide *adequate remuneration* and better regulations for the prevention as well as for the cure of disease among the poor. Such provisions are due from the State on the score of justice, humanity, and sound economy.

"THOMAS HODGKIN, M.D., Chairman.
"CHARLES F. J. LORD, Hon. Sec."

There are three serious obstacles with which, it appears to us, the Committee have to contend:—

1. The want of co-operation on the part of the great majority of Union medical officers; 2. The indifference of Government Boards; and 3. The "Guardian" interest in Parliament.

With regard to the first,—it ought not to exist. It is admitted by all that the remuneration of Union officers is insufficient, and the labour excessive. These are assuredly evils which require removal. Is there any Union Officer so selfish that he would profit by the results of efforts, if successful, while he will lend no helping hand to the disinterested few who are now exerting themselves for his benefit? The Report leads us to infer that a large majority are disposed to work on in their present abject condition. If so, there can be no hope of a change for the better. With respect to the two remaining obstacles, we think they would soon cease to exist if the Union surgeons cordially united for the protection of their own interests. Boards of Guardians find a ready justi-

fication for their harsh dealings with their medical officers in the existence of a most degrading and unprofessional system of competition, in which honour is sacrificed for the sake of a paltry salary.

Reviews.

Gout: its Causes, Cure, and Prevention, by an original and most successful treatment, founded on the organic changes in the human solids, and on the functions of the skin; without the use of Colchicum. By ABRAHAM TOULMIN, M.D., &c. 12mo. pp. 112. London: Highley. 1850.

FROM the nature of the above title-page we are led to suppose that this work is addressed rather to the non-professional than to the professional reader. A glance at its contents gives strength to the suspicion. The first three chapters consist of a popular sketch of the chemistry and physiology of food and digestion, assimilation, &c. The two following chapters are on the causes of gout. The next on the functions of the skin. This is succeeded by an exposition of the author's original mode of treatment, which he terms *didermic*. The theory on which the author bases his treatment is, that the blood is to be depurated by increasing the functions of the skin. The practice founded thereon is the use of the *Thermaclin*, or air-tight hot-air bed, to promote profuse diaphoresis. This method the author claims the merit of having introduced into this country, being, it seems, unacquainted with the simple apparatus devised by Dr Copland, in 1832, for the use of cholera patients; and which we have ourselves, since that period, frequently made use of in treating chronic rheumatism and rheumatic gout.

Mr. Toulmin concludes with some common-sense propositions on the prevention of gout; and gives a series of cases in illustration of the benefit of his *thermaclin*, of which, however, we find no particular description, and we are therefore left in doubt whether a special apparatus be indicated, or the

term be employed generally to signify hot air baths or beds.

Ship Fever, so-called: its History, Nature, and best Treatment. By HENRY GRAFTON CLARK, M.D. Pamphlet, 8vo. pp. 48. Boston. 1850.

THE ship fever, as seen on board the emigrant ships, in the quarantine hospitals, and among emigrants newly arrived from England and Ireland, in the ports of the New World, is said by Dr. Clark to be clearly different from anything that has been before known in America. "It is the opinion of the writer that, under the various titles of jail, hospital or camp fever, putrid continual fever, maculated typhus, and English or Irish typhus, is expressed the identical disease known recently and popularly under the name of SHIP FEVER."

The author, in pointing out the differences between typhus and typhoid fever, states that the distinction has not been made in England; but, if not before, it has recently been accurately made by Dr. Jenner in his papers on typhoid fever.

The characters of the disease are briefly and clearly depicted, and the pathological appearances are accurately described. The treatment recorded is judicious.

CAUTION IN THE USE OF ETHER AND CHLOROFORM.

A VERY serious accident happened in surgical practice in Boston, U.S., not long since, by the taking fire of the vapour of the ether which was used to produce insensibility. The circumstances under which the accident occurred are these:—The patient had an operation performed upon the face, near the mouth. There being some considerable hemorrhage, the actual cautery was applied; and it was by contact with the heated iron that the ether vapour was set on fire. Too much caution cannot be used in the application of ether; and this one instance of its inflammability in actual practice should serve as a caution to all. No lighted body should be placed near a patient, while he is under the influence of ether. There never should be a lighted lamp brought into a close or small room while etherization is going on.—*Boston Medical Journal*

*Medical Trials and Inquests.*SUPREME JUDICIAL COURT,
BOSTON.

March 19, 1850.

REPORT OF THE TRIAL OF DR. WEBSTER
FOR THE MURDER OF DR. PARKMAN.*Before Chief Justice Shaw and Justices
Wilde, Dewey, and Metcalf.*

[Concluded from p. 473.]

DR. JEFFRIES WYMAN, sworn. — I am professor of anatomy in Harvard University; have been a teacher of anatomy for the last eight years. First went to the Medical College on Sunday, the 2d of December. I had given to me the charge of the bones found in the furnace; made a catalogue of them. These bones in this box are the bones. I was not called specially to the other parts of the remains. [The witness explained a drawing of a skeleton, in which the bones found were marked in yellow, represented by the shaded portions of the subjoined engraving.] There were no marks of the

body being a subject for dissection: it struck me that the sternum was taken out as it would have been by a physician at

an ordinary post-mortem examination. I was also struck with the separation of the sternum from the clavicles, or collar-bones, and first rib; the route for the knife to pass through is so difficult, that a person having no knowledge of the structure of the parts would not have been likely to direct it in that way. I did not feel myself called upon to examine critically. I should consider the person past the middle age of life. On examining the thorax and turning it over, I was struck with the quantity of hair on the back; I never saw a person before with so much. If a person was killed by a blow, and then stabbed immediately, there would have been a flow of blood according to the vessel wounded, and the depth of the stab. A post-mortem examination may be made without an effusion of blood, if made with care. I made an examination of certain spots on the side of the staircase, near the lower landing; they were not blood but tobacco-stains. This has no reference to the spots found higher up. Saw spots, which I was told by a chemist were nitrate of copper; did not examine them. I performed some experiments on the effect of nitrate of copper on blood. Blood is known by red flattened globules, or discs. I placed some blood under the microscope, and applied nitrate of copper in solution. The action was not immediate; after a few hours it took place, and the blood discs disappeared. I should say that nitrate of copper would destroy all characteristics by which blood could be detected by the microscope. There were no other spots in the building on which were any marks of blood, or what was recognised as such. [Witness was shown some slippers, on which were spots supposed to be blood.] They are the same from which I cut portions having similar spots, which I examined, and found what I considered to be blood. [Pantaloons were shown, marked with the name of Dr. Webster, which the witness identified as the ones from which he cut pieces.] It was the right slipper that was bloody, and the left leg of the pantaloons, on the bottom, on the outside. The slipper had also what looked like Venetian red on the sole. The pantaloons had another spot, which might be Venetian red, but which seemed to be rather a mark of acid. The blood did not seem to have fallen from any height, for it had not trickled down. There was a piece of paper found in the laboratory, with two spots of blood. [The witness explained the classification and arrangement of the bones, referring them to the different parts of the body.] The first bone belonged to the front of the forehead. [Witness explained how he knew it to belong there.]

The next was a piece of the temporal bone, known by the canals that pass through it. The next was behind the ear. [The witness proceeded to demonstrate the places of the bones, and succeeded in putting together three fragments, which form the greater part of the right-half of the lower jaw.]

Attorney-General.—Please state to the Jury whether there is anything remarkable in the correspondence of this jaw with Dr. Keep's model.

Witness.—I made a drawing of the jaw before I saw the model or knew of the condition of Dr Parkman's teeth. There was an absence of the teeth from the coronoid process to the first molar, or bicuspid; I was not absolutely certain which, but my impression was that there were three teeth gone up to the bicuspid. I made a drawing in a pencil of a bicuspid, as a probability. On comparing the fragments of bones with the model, I found that Dr. Parkman had lost these teeth. They seem to correspond in this respect; as the model was taken from the mouth when the gum covered the bone, we cannot expect an exact correspondence. If the curves of this jaw had been carried out, as we should expect, by analogy, it would have given a rising chin. The portion of the left lower jaw had a remarkable depression; have not witnessed the same in any other jaw, having examined a hundred and fifteen or twenty of them, perhaps with particular attention to the jaws. There were several vertebrae, a joint of an elbow, some bones of the wrist, some joints of the fingers, part of the bones of the right leg known unmistakably to be such by their character; there were not duplicates of any bone, nor were there any bones except of the missing parts not found in the vault or tea-chest. There were some fractures, which had the appearance of having been made before calcining. Before calcining, the animal matter adheres; there is a greater disposition to splinter, and to angular forms rather than to crumble. [The witness showed the jury a fracture of a skull-bone, which had the appearance of being fractured before being calcined. He did not think the sign was absolute.]

By the Court.—Does your distinction refer to the fractures made before and after death?

Witness.—Before and after calcination only.

Cross-examination.—In a half-calcined bone there is less disposition to crumble. Thinks nitrate of copper effectual to remove blood, but not so good as water, unless the wood were to be destroyed. Should think muriatic acid a better solvent of blood, as it is of animal tissue. *Physiologist.*—*then nitric.* *that the*

blood is about the fifth part of the weight of the body; thus would be 28lbs. for a body of one hundred and forty pounds. This is by no means a precise statement; but twenty-five pounds have been actually obtained, and probably not all was obtained. There was a thorough examination of the laboratory for blood. I superintended the taking up of the brick floor, which was laid in sand. Found no traces of blood. Took chips from the floor to examine; found no blood on them. Should think the cutting to pieces indicated that the person doing it had some knowledge of anatomy, and knew where the joints were to be found. If blood had fallen from the height of three feet, it would have given an oblong mark, falling on a vertical substance; could not tell from the blood-marks, how long it had been on. After a day or two, blood-marks assume a brown colour; after that, they do not change for years. The microscope distinguishes human blood from the blood of the lower animals, but not from that of the higher, as the ox.

Dr. OLIVER W. HOLMES, sworn.—I am Parkman Professor of Anatomy and Physiology in the Medical School. The professorship is named after Dr. George Parkman. The dedication of the Medical College must have been on the first Wednesday of November. Noticed Dr. Parkman's teeth on that occasion, as new; they were white and long. Dr. Webster lectures to the Medical Class four times a week, on the subject of Chemistry. His lecture-room, laboratory, and small room in the rear, form an establishment entirely distinct from those of the other Professors. He never had any need of anatomical subjects. The remains indicated that the person who separated them knew where to cut; there is no botching about the business. Noticed a discolouration, which seemed to be the effect of heat; was told, and readily believed, that it was the effect of a caustic substance. Was familiar with the form of Dr. Parkman; did not see any particular similarity between the parts and Dr. Parkman, or anything dissimilar. A stab between the sixth and seventh ribs would not necessarily reach the heart. If it did, there might be more or less effusion of blood externally, according to circumstances. If the wounds externally and internally corresponded, there might be external effusion: if the external wound slipped over the internal, the effusion would be chiefly internal. My lecture-room is over that of Dr. Webster; have never heard noises from his room. The students in my room sit on rising seats; I stand on the floor.

Cross-examination.—Could not know what the effusion of blood would be, without knowing the direction of the knife; if the

knife touched the heart, much blood would be inside, but not probably all. Have heard the noise of students below, when in the demonstrator's room, which is at the head of the stairs. Cannot say that the hair had been singed by fire. Am not so familiar with the effects of caustics as to say what effect could be produced by them; but was prepared to believe that all I did see had been so produced. A mortal blow might be struck on the head, and no effusion of blood take place.

[The defence of the prisoner chiefly rested upon an *alibi*; it being alleged that the deceased had been seen by credible witnesses alive and well some hours after the time at which it was stated he must have been murdered. It was further contended that the remains were not identified as those of Dr. Parkman, and that the dental evidence was not trustworthy. Admitting, however, that the jury were satisfied on the question of identity, it was suggested that the real cause of death had not been proved, and that, at all events, there was no evidence of a premeditated design to kill on the part of Dr. Webster; that he and the deceased might have quarrelled concerning the debt, and that in the heat of passion the prisoner might have struck him a fatal blow. The concealment and disposal of the remains might be ascribed to the want of presence of mind on the part of the prisoner how to act in such an emergency. We do not publish the arguments thus ingeniously urged at considerable length, because since his conviction the prisoner has acknowledged that the remains were those of Dr. Parkman, and that he fell by his hand. Even without this confession the arguments were founded on such improbable assumptions, that they only served to indicate the impossibility of giving a clear and satisfactory answer to the evidence for the prosecution.

The prisoner himself addressed the jury, by permission of the Court, before the judge summed up. His address did not touch the terrible charge against him: he did not venture to deny the crime, but merely offered a few remarks explanatory of trivial and unimportant points in the circumstantial evidence.

Some of the medical gentlemen who had given evidence for the prosecution were called for the defence, but their testimony did not in the least alter the force of the evidence in support of the charge. In the closing argument of the Attorney-General there occurs a passage for which we must find room. It involves a high compliment to the profession on scientific evidence, and on the unselfish character of medical researches when required for the purposes of public justice. In speaking of the proofs

of guilt, we find the learned gentleman saying—]

If anything more were needed, it is found in the conformity of the jaw of Dr. Parkman to the mould which Dr. Keep had; which mould corresponded with all the peculiarities of the jaw of Dr. Parkman, picked out from the smouldering ashes, and, by that true lover of science and uncompromising seeker of the truth, Dr. Wyman; put together, and produced here before us. If he had produced here Dr. Parkman's right hand, with a scar upon it which every one of his friends had known, the evidence of identity could not have been more conclusive. When we consider that here is a man in this culprit's dock, with such advantages of education and of culture as he has enjoyed, who is himself a devotee of science,—and we feel that he has so debased and betrayed his high vocation and mission as to have slain, either in anger or in cold blood, whichever it may be, his fellow-man, and his benefactor and friend,—it almost sickens us; we feel that there is no shield for any of us against the commission of great crimes; that culture, science, and all the ennobling and purifying influences of education, are utterly lost upon us. To find them subjected to such base uses as that chemist's laboratory has witnessed, prompts us to exclaim, with the poet,

"Oh, star-eyed science! hast thou wandered there
To waft us back the tidings of despair?"

But we recover and are refreshed only when we go to the other fact which this case discloses, that, although science had been debased to the purpose of destroying those remains, yet science, in its true vocation, in its nobler scope, sifts and penetrates those smouldering ashes, and evokes from them those materials with which it reconstructs almost the entire body which science had vainly attempted to destroy. This gives to us a renewed assurance of respect for science! And I cannot pass from this part of the case without expressing a feeling which has been often in my mind during the solemnities of this trial—the honour that is due to that noble profession through whose ministers this assurance has come to us. When we have welcomed them to our bedside, amid our trials and sufferings, we have loved and honoured them; but when we meet them here, and see them taking the stand, as they do, most reluctantly, against one of their own brotherhood,—forgetting, or rather trampling under foot, all those considerations which arise from caste, from class, and giving themselves unreservedly to the truth, let it strike where it may, let it fall where it will,—they challenge and are wor-

thy of the highest honour; and they have my humble reverence. One of their number, whom we looked to have been here, and whose aid, in another recent capital trial, I had occasion to seek—in which his testimony showed how much he would have added to the impressiveness of this—has passed away from us since these investigations commenced,—a man who honoured the community in which he lived, who honoured the profession to which he belonged, and who, for the cause of science, has been removed from us too soon,—I refer to the late Dr. Martin Gay, whose testimony to that comes down in yonder prison, and over at that Medical College, would have been as valuable to us as would his scientific testimony upon the question of the identification of the remains.

[The only part of the summing up by Chief Justice Shaw which requires notice, is that which refers to the proof of identity from an examination of the jaw and teeth.]

It is scarcely necessary for me (observed the learned judge) to do more than name the witnesses which have been called to testify upon that subject. It is certainly a very interesting inquiry, whether the teeth can be identified or not. It cannot have escaped notice, how great a similarity there is in this to the investigation of what are called fossil remains. Persons have studied the anatomy of the bodies of reptiles, and of the lower orders, to such a minute degree, that from the figure, from the openings, they are able to say, from a single bone even, what class they belong to, and thus trace the inquiry, and ascertain the existence of races and species of animals. But still you are told here by the anatomists,—by Dr. Jeffries Wyman, who is reputed to be excellent,—that by finding a small piece of bone, it is possible to determine to what part of the body that belonged. There are particular parts through which particular nerves or vessels pass, by which it can be determined that they are parts of the temporal bone, the cheek bone, or some other. Dr. Keep was called, and stated that, three years previously, in 1846, he made teeth for Dr. Parkman, to whose teeth and stumps various adjustments were to be made. He testifies that they were adjusted and fitted. Now, the gold having been melted, but the blocks of teeth remaining, with several peculiar angles and points, the question was, whether he could ascertain their identity. It is merely necessary for me to refer you to his testimony. He was of opinion that he could identify them; he was satisfied that they were the teeth of Dr. Parkman. If you are satisfied that that conclusion was right, then this testimony is of a very different character from that of the shape

and size, and has a strong tendency to prove that it was the body of the deceased person. I barely refer to the persons who have testified to this. Dr. Keep, and his assistant, Dr. Noble, think that they can identify these blocks of teeth. Dr. Morton is of opinion that there is not enough to enable an artist to identify them. And with regard to all that, Drs. Harwood, Codman, and Tucker, have testified the other way. You are to determine, by all the testimony, whether those were the teeth of Dr. Parkman, and belonged to the same body as the other parts; and, if so, it has a strong tendency to a proof of death by violence, and then the *corpus delicti* is established; otherwise, not. If this is not proved to the satisfaction of the jury, beyond reasonable doubt, then the dead body is not proved to be that of Dr. Parkman. . . .

If this act of homicide was committed by Professor Webster, and there is not sufficient proof to mitigate the crime to manslaughter, then the conclusion would be that it was murder by implied malice. If the other assertion is proved, that it was intended to decoy him to the College to do this deed, that is express malice. If it is not proved that he was there, then there must be a general verdict of acquittal.

[The trial occupied twelve days. The prisoner was unanimously found GUILTY; and he was executed at Boston, as we have already announced, on the 30th ult. Subsequently to his conviction, he confessed that he had killed Dr. Parkman under circumstances of great provocation. An appeal was made to the Committee on Pardons for a commutation of punishment: they made the subjoined report:—]

"The Committee respectfully report that they cannot, consistently with what they conceive their duty, recommend a commutation of the sentence in the case of John W. Webster, as prayed for in his petition. Nothing now remains for the Committee, in the discharge of this painful duty, but to advise your Excellency in determining upon a time for the Execution; and they name *Friday, the thirtieth day of August next*, as the day; and recommend to your Excellency to decide upon that day as the time for the execution of John W. Webster.

"JOHN REED, Chairman.

"Council Chamber, July 19, 1850."

THE CHOLERA AT MALTA.

LETTERS from Malta of the 8th inst. state that the cholera, which had considerably diminished, had for a day or two been on the increase. Its reappearance was attributed to a whole day of rain, followed by a north-west wind, which occurred last week.

Correspondence.

ON THE SUPPOSED VALUE OF ALCOHOLIC LIQUORS IN MAINTAINING THE HEAT OF THE HUMAN BODY UNDER EXPOSURE TO SEVERE COLD. BY WILLIAM B. CARPENTER, M.D., F.R.S.

I HAVE recently perceived with much regret, that the value of the evidence collected by myself and others, in disproof of the popular opinion which attributes to alcoholic liquors a power of assisting the human system to sustain extremes of cold, has been, in my apprehension, very much underrated; and that the medical profession is less well-informed upon this point, than might have been anticipated from its scientific as well as practical interest. In the review of my "Prize Essay on Alcoholic Liquors," in the *MEDICAL GAZETTE* (p. 203 of the present volume), the following passage occurs:—"Dr. Carpenter argues, from the facts of organic chemistry, that alcohol cannot either enable the human body to endure cold, or contribute to the maintenance of its heat; but 'universal experience' refutes the speculation; and we may observe, that experiments which Liebig performed directly with reference to these very points led him to the very opposite conclusions." It is a little singular that another reviewer of my essay (*Dublin Quarterly Journal* for August, p. 164) should have given a precisely opposite statement of my opinions:—"We have not time to discuss the power of alcohol in enabling the body to resist the depressing influences of cold and heat. This we the less regret, as Dr. Carpenter observes that its power in the former of these cases 'is, perhaps, the best established of all its attributes.'" This reviewer would not seem to have read beyond the first sentence of a section, in which I proceed to demolish this very proposition.

I beg that I may not be understood as now bringing forward this subject with the purpose of complaining of these or of any other of the reviews of my Essay. I was well aware that it would run counter, in many points, to the ideas currently entertained in the profession, and that the production of it would not advance my own scientific reputation—in fact, would probably diminish it: and nothing but the desire to do something, however little, towards the reduction of that great mass of individual and social evil which is clearly traceable to the abuse of intoxicating liquors, leads me now to come forward, for the purpose of again stating, briefly but

explicitly, what are the opinions upon this subject which my own inquiries have led me to embrace, with the nature of the evidence upon which they are founded, and to place before the profession some additional evidence which has come before me since my essay was published.

The question which I had to answer was, what *science* and *experience* teach in regard to the heat-producing powers of alcohol. Now, at the first view, those who adopt (as I do) the chemical theory of animal heat as being true in the main, though not accounting for every phenomenon, would naturally look to alcohol as one of the most potent of all *fuels*. As oleaginous substances produce more heat in combustion than saccharine, so does alcohol (in virtue of its larger proportion of hydrogen) produce more heat than oil or fat. But the experiments of Dr. Prout, and of Vierordt, have shown that the amount of *carbonic acid* exhaled after taking alcoholic liquids is *considerably diminished*; and hence it appears that, whilst alcohol is in the blood, the oxygenation of other combustible materials is retarded (an inference confirmed by the fact ascertained by Bouchardat, as to the venous character of the blood when alcohol has been introduced into the system in excess); so that, notwithstanding the larger proportion of *water* which may be formed by the combusive process, it is doubtful whether more heat is generated by the elimination of alcohol through the respiration, than by the combustion of oleaginous matters. Considered simply as a fuel, then, it has not the advantages it would at first sight appear to possess: but I expressly point out that it has a special value in certain cases, in which there is a deficiency of other combustible material in the blood, and in which it is burnt off so rapidly that it has not time to exert its stimulating property.

Now it is because alcohol is not (like oleaginous matters) a *mere* fuel, but because it exerts a stimulating action on the system, that its effect is considerably different from that of other combusive materials. The pleasant glow which it temporarily produces, seems due, in part, to the increase in the rate and force of the circulation, and partly (it may be) to its stimulating influence on the nervous system. In this way the depressing influence of cold may be effectually resisted *for a time* with its assistance, but *only* for a time; for, as sure as there is stimulation, there is subsequent depression; and, if the exposure to cold be prolonged, its severity will be more felt, and it will be more injurious during that period of depression, than if the alcohol had not been taken.

This I affirm to be the teaching of

science upon the question. It is stated that in so doing I am placing myself in opposition to the dictum of Professor Liebig, who seems to put an unlimited faith in the heat-producing powers of alcohol,—looking at it only in its chemical relations, and ignoring altogether its physiological action. But I am yet to learn what are the experiments on the strength of which it is so confidently asserted that he has been led to opposite conclusions; and, until I shall have been made acquainted with them, I venture to think that the opinion of a physiologist upon a physiological question may be set against that of a chemist, however eminent.

I would not for a moment affirm, however, that any such *a priori* argument should furnish our rule of practice. If “experience” unquestionably led to a different conclusion, I would at once say that our science was imperfect, and must be reconstructed. What science can be good for anything, that is inconsistent with experience? But I find experience here in the fullest harmony with scientific prediction. I cite in my essay the testimony of three distinguished medical officers—Sir John Richardson, Dr. Richard King, and Dr. Joseph D. Hooker, who have been attached to Arctic and Antarctic expeditions. This testimony was kindly given to me in reply to inquiries which I put to these gentlemen. I did not select them as previously knowing their opinions, but because I knew them to be men far above the average in intelligence, as well as to have had special experience on this particular question; and because I happened to have an amount of personal acquaintance with them, which justified me in going to them for information. The statements which I have given on their authority are not selected pieces of evidence, but are all I could get: and they are all most explicit to the same effect—that, whatever may be the temporary warming effect of spirituous liquors, the use of them diminishes the power of resisting cold. I should like to know who has a better claim to be heard on such a question than Sir John Richardson, the companion of Franklin in that disastrous overland journey which put the endurance of every individual to the severest test. Or what experience can be set against that of the servants of the Hudson’s Bay Company, who have for some years past entirely disused spirits, to the great improvement, as Sir John Richardson informs me, of their health and morals?

Surely those who speak so confidently of the refutation of my “speculation” by “universal experience” are bound to get up some sort of case to meet evidence of this kind, and should not be permitted to

cast it on one side as unworthy even of notice. Several other facts, which I have ascertained by personal inquiry, are contained in my Essay;* but rather than cite these, I shall now adduce a body of additional evidence, which will, I think, lead those who will peruse it to question whether the usual notions are quite as well founded as they are accustomed to consider them.

Happening last Easter to receive a visit from Sir John Richardson, I inquired from him how far the experience of his last expedition (undertaken two years ago in search of Sir John Franklin) corresponded with the statement he had given me before he proceeded upon it; and, in reply, he assured me that it had most fully confirmed him in his adhesion to the Total Abstinence system as the best for the endurance of severe and continued cold, the whole party having sustained the full severity of the Arctic winter in a manner in which he was confident (from his former experience) they could not have done, if even a moderate allowance of spirits had been employed. He mentioned, as a proof of his own power of resisting cold, notwithstanding his advancing years, that he was accustomed every evening, during the residence of the party at winter quarters, to cross from the dwelling-house to the observatory at a short distance—going out from a room of the temperature of about 50° into an atmosphere of —50° (that is, enduring a change of a hundred degrees) without even putting on his great coat.

In the narrative of “An Arctic Voyage to Baffin’s Bay and Lancaster Sound in search of friends with Sir John Franklin,” by Mr. R. A. Goodsir (brother of the distinguished Professor of Anatomy in the University of Edinburgh), the following passage occurs at p. 138:—“Well pleased were the men in the evenings if they had a breeze sufficient to bring them back, but generally speaking their weary arms had to supply the motive power. But happy enough they seemed to be when they got on board: the boats were cheerily hoisted up; then each and all betook themselves to the infusions and decoctions of their tea and coffee, the whaling sailor’s greatest luxury and comfort. He has no objection

* My reviewer in the MEDICAL GAZETTE wonders that I have not performed “a new series of experiments” in support of my views. Surely he has not considered that such experiments as have been, and are now in progress, afford all the information required. Could either Professor Liebig or I determine by experiment the heat-producing powers of alcohol in the living human body, by any experiments short of a residence in the Arctic regions? And is not the experience of scientific men who have lived for months at a temperature of —50° as valuable a result as if they had been sent there on purpose to put this question to the test?

to his grog; but I think he has, long ere this, found out that *not strong tea or coffee*, particularly the former, is by far the best beverage he can take in these climates."

Much evidence to the same effect was recently given before the Committee appointed by the Board of Admiralty "to inquire into the expediency of diminishing the present quantity of spirits served out daily to the seamen in the Royal Navy." The witnesses were officers of various grades, medical officers, and seamen,—all of them *practical men*, speaking from their own experience and that of the service generally, and none of them (so far as I can gather) abstainers on principle. Their testimony is, therefore, peculiarly valuable. I cite *all* that I can find bearing upon this point, that I may not be accused of *selecting* facts to suit my purposes. Much of this evidence applies less expressly to *cold*, than to the ordinary exigencies of a seaman's life, of which exposure to cold, wet, and fatigue, is among the most common.

Captain Chadwick, Commander of the American packet-ship "Sir Robert Peel," examined.—Q. 222. "Have you ever been in a ship in which there was a total discontinuance of the use of spirits; and, if so, was it satisfactory to the men?"—A. "For the last twelve years I have sailed on the strict principle of temperance, and have found it work well, and no complaint among the men, and have had men from all European nations among my crews." Q. 225. "Do you think, from your experience, that the temperance system, as it is called, worked well, and without discontent amongst the men?"—A. "I am quite sure that in all our merchant service it works well: even in our *whaling ships*, of which there are near 700 vessels, there is not one in twenty in which spirits are allowed; and thus far they have been very fortunate in their voyages, which are from two to four years, generally cruising in *all climates* where their voyages can best be accomplished."

James Yeo, Esq., shipowner, from Prince Edward's Island, examined.—After mentioning the reasons which had induced him to diminish the allowance of grog in his ships, and to discontinue it entirely for the last two years, he states that the habitual allowance of the men is tea and sugar morning and evening, with an allowance of coffee when there is heavy work, in a wet night, or in a gale; and that no pecuniary compensation is allowed. Nevertheless, he has no difficulty in procuring good hands; and, being asked (Q. 289) whether he finds the same men constantly coming and continuing in his service, he replies, "The same men, and they get better satisfied after a voyage or two without the grog

than with it." The same practice (he says) is adopted in Nova Scotia and New Brunswick generally—localities in which it has been affirmed that the assistance of alcoholic liquors is particularly needed, on account of the cold damp fogs which are so frequent there.

Captain George Denny, brother-in-law of Mr. Frederick Green, the great shipowner of London, and formerly commander of one of his ships for twenty years, examined.—He states that the temperance principle has been tried in Mr. Green's employ, but found not to answer, from the unwillingness of the men.* The following is his opinion as to the effect of the substitution of coffee or cocoa for spirits:—A. 360. "We find that on giving a glass of grog, when any extra exertion is required, the men go more cheerfully through their work at night, such as reefing topsails, and they are very slack if you do not give them a little spirit." Q. 361. "Do you not think that on a cold night, if they had coffee or cocoa made for them, that it would be as useful?"—A. "They would then have to wait for the coffee or cocoa." Q. 362. "But when you expected a heavy night, you might have it in a state of preparation?"—A. "I think it would perhaps be better for their constitutions. I do not think that it would give them the same zest for their work." Q. 363. "Not so exhilarating?"—A. "No."

I would remark that Captain Denny's experience was, by his own showing, derived from a crew which had come into the system *unwillingly*; and it does not appear that the allowance of spirits on such an occasion had any other than a *mental* effect. Captain Chadwick and Mr. Yeo, who worked with *willing* crews, found the men just as well, or better, without it; and even Captain Denny allows that the coffee or cocoa "would perhaps be better for their constitutions."

Captain Cospatrick Baillie Hamilton, R.N., examined.—The evidence of this officer principally went to show that a great decrease in punishments in the Navy might be expected from a discontinuance of the spirit allowance. "I would sum up my opinion (he says) in these few words, that if we would reduce corporal punishments in the Navy, our first step should be to throw overboard the grog." Q. 444. "Have you anything to add to your evidence?"—A. "I would only mention that, on the occasion of my taking a passage in a merchant ship, spirits were not issued. The name of this vessel was the 'Maid of

* It appears that the trial was made, and the attempt abandoned, *some years ago*. The result would be probably different now. See the evidence of Lieut. Brown, R.N.

Mona.' I went in her from the Cape to Rio in 1844. We had severe weather off the Cape, but no spirits were issued. The crew were very cheerful and well conducted, and the master was an abstemious good man, and a thorough sailor. Some of the crew had been man-of-war's men, and one had deserted from the Navy. I spoke much to these men: they said they were well paid, well fed, and had a decent captain, and did not wish for spirits. They said they all liked their glass as well as others, but preferred good wages on the whole. I felt secure and comfortable on board that vessel, on account of their being no spirits. It was on this occasion that I was particularly struck with the advantage of a ship sailing without spirits on board; and from that time I have considered it as idle to say that seamen are necessarily happier or more contented from being supplied with grog."

Captain Peter Richards, R.N., examined.—Q. 750. "Do you suppose that spirits tend to support a man when labouring hard?"—A. "I should think they would stimulate a man." Q. 751. "Do you not think that tea or coffee, or cocoa, would have the same effect?"—A. "I dare say they would equally well, if you could persuade the men to take them." Q. 795. "Should you think it beneficial to the service if there were a discretionary power left with the captain to issue, under peculiar circumstances, coffee by night?"—A. "No doubt of it. I should prefer that greatly to a permission to issue grog." Q. 796. "Would it not be attended with great inconvenience to get fires at night in bad weather?"—A. "It so seldom happens, that I should think that under a necessity the inconvenience of getting fires ought not to be thought of."

Lieutenant J. H. Brown, R.N., Registrar of Seamen, examined.—The evidence of this gentleman, whose position has enabled him to acquire the most accurate and comprehensive knowledge of the habits and feelings of British seamen, shows that a great change is taking place in these in regard to the allowance of spirits. "Formerly they invariably demurred, and it was difficult to get a crew to sign the articles with such conditions; but within the last three or four years a change of feeling has gained ground to such an extent that, with the exception of some of the Steam Companies* and large shipowners, nine-tenths of the ships which sail from the United Kingdom have the stipulation,—either "no

grog" or "grog at the option of the captain." "The Committee will find, by the answers of the shipping agents throughout the United Kingdom, that such is the general feeling of the sailors, that they do not at present demur to sign articles where no spirits are allowed."

It is impossible to suppose that such a change should have taken place,—not suddenly, under the influence of enthusiasm or excitement, but gradually, and almost imperceptibly,—if the "universal experience" of the parties concerned had demonstrated that the discontinuance of the spirit-allowance had been in any respect otherwise than beneficial to them; it being to be borne in mind that the system is repugnant to the *tastes* of the class at large, and of the great majority of individuals.

WILLIAM COLES, gunner's mate in the "Rodney," examined—Q. 1159. "Do you think it would do, if it were to be the custom, instead of 'splicing the main-brace' in heavy gales, to have a cup of coffee given to the men at night who may get wet?"—A. "In a small vessel oftentimes the hands are turned up to shorten sail; they generally get wet before they have done the work. When a man comes down from aloft, after being half an hour shortening sail, I consider that a glass of grog enlivens a man."

Captain EDWARD TATHAM, R.N., examined—Q. 1320. "In bad weather what would your opinion be if coffee were issued to the men?"—A. "I think there would be a difficulty attending the making of it, but that a large portion of the men are very fond of it." Q. 1321. "Supposing any accident happened in a ship, for instance a mast or a yard being carried away, and the whole ship's company were employed, one of the means of refreshing the men that has been mentioned was that of making a small copperfull of coffee, and serving it out to them?"—A. "It is a capital thing if it can be done; giving them coffee or tea would be most popular, and they would like it, I am certain."

JOHN BELLOWES, a quarter-master, who has been in the service twenty-one years, states that he left off grog many years ago, from seeing his partner fall down and hurt himself whilst reefing top-sails. "I saw directly it was through the grog, and I saw that it was an evil; and I said, 'From this time I will have nothing further to do with it.'" Q. 1610. "When there is any severe weather, and on extraordinary occasions, if hot coffee were given at night, instead of 'splicing the main-brace,' would that be more satisfactory to the men?"—A. "It would be much better than grog. Before we came round Cape Horn the officers said that I should be glad to drink grog when I got to Cape Horn; but I found that I could

* The Peninsular and Oriental Steam Navigation Company has recently introduced the temperance, or rather *abstinence*, principle into the numerous ships in its employ.

do my duty without it. I was not on the doctor's list, and I did as well as the rest, and I used to stand four hours at the wheel."

ROBERT W. ROBERTSON, petty officer, 14 years in the naval service, examined—This witness had also served in four merchant vessels in which no spirits were allowed. He states that the system is increasing in the merchant service generally, and that he has heard no complaints in any vessel that he has been in. Q. 1759. "Did they ever give you coffee in bad weather instead of spirits?"—A. "It is customary in many ships to have coffee in lieu of spirits, at night time in particular, when the watch are roused out of their beds." Q. 1761. "Do you think coffee a more comfortable and nourishing beverage for the men than spirits after the sort of weather you have been describing?"—A. "Yes, I think it is; I have had it once or twice at my own expense on the passage home."

GEORGE MURRAY, quartermaster, of 16 years' standing, examined—Q. 2974. "During your late employment in the Arctic regions, was there an additional allowance of spirits occasionally served out?"—A. "Occasionally." Q. 2975. "When the temperature was very severe, or on what occasions?"—A. "Generally when towing. We were towing during the whole of the day, perhaps, from 8 o'clock in the morning until 12 o'clock at night; and Sir James Ross generally used to issue an additional half allowance of spirits, or to some men individually who might fall off the ice." Q. 2977. "But not for mere cold?"—A. "Not for mere cold: I do not think it is of any good against the cold." Q. 2978. "Would the men have liked any hot drink better, do you think, such as hot coffee?"—A. "I doubt much whether seamen would not rather have a glass of grog than hot coffee. I should prefer the coffee myself, and I dare say that a great many others would; I have no doubt of it."

DR. JOHN ROBERTSON, surgeon, R.N., 22 years in the service, examined—Q. 2243. "The present allowance being a quarter of a pint of spirits a day, to what would you recommend it to be reduced—to one half?"—A. "Yes, I should say one half: I should think the more it was reduced the better it would be both for their health, strength, and general welfare, if it cannot be done without altogether." This gentleman served in the "Enterprise," in the last Arctic expedition under Sir James Ross; and states that there were men in that ship who never drank their allowance of grog; also, that seamen generally do not care so much about their grog as they used to do, and that "the better sort of men are much more satisfied

with the allowance of tea."* Q. 2256. "Do you consider that in the ships employed in the Arctic regions, spirits are necessary for the men at all?"—A. "I should think so, certainly. At certain times spirits are highly useful in the Arctic regions, where the men suffer a great deal from wet, cold, and fatigue. I find that it assists in stimulating the nervous system and reviving their energies." Q. 2257. "Would it not be better to give them hot coffee, or cocoa, or tea, after such exertion, in preference to spirits?"—A. "Yes, I think so, undoubtedly; hot coffee or tea would be preferable. What I meant was, that they should have some comforts to recruit their strength." Q. 2258. "You think that would be decidedly preferable to spirits under all circumstances?"—A. "Yes, decidedly; unquestionably they require some indulgence on these occasions." Q. 2259. "What do you call indulgence?"—A. "Some restorative, as tea or coffee, but, where this cannot be had, spirits. It may be observed here that the limited amount of fuel will not admit of frequent hot messes in the Arctic regions."

MR. JAMES DONNET, surgeon, R.N., 10 years in the service, examined—Q. 2323. "After rainy weather, and when the men perhaps have been up all night, or half the night, which would you recommend as preferable, 'splicing the main brace,' or giving them a basin of hot tea or cocoa?"—A. "I would recommend warm tea, it is proved to be the most invigorating beverage in such cases." Q. 2324. "You are no advocate at any time for serving an additional allowance of spirits?"—A. "There may be some particular circumstances where a man may be much benefited; he may be so debilitated from the work that he might require spirits. I have heard one of the officers of the 'Quail,' which was wrecked in 1836 in the Bay of Biscay, say that for ten days she lay as a wreck on the water; the man at the helm was obliged to be lashed, from the sea at times making a clean breach over her. During this time they were offered grog every hour, and warm tea. All of them refused the grog and drank the tea, not that they disliked grog, but tea proved in their case the most invigorating beverage."

This witness is now serving as surgeon on board one of the ships despatched this spring to the Arctic regions in search of Sir John Franklin. All these expeditions are sent

* All the witnesses concur in stating that, since tea has been issued in the evening, scarcely any of the men care for the allowance of grog which is issued at the same time; and this consequently becomes the perquisite of the cook of the mess. To this system most of the witnesses attribute the greater part of the drunkenness and dissipation which occurs on board ship.

out on the "temperance" principle,—a pretty plain proof that the Admiralty (a body not particularly easy to move, as our profession knows to its cost) is well convinced of the special adaptation of this system for crews serving in the coldest climates. I happened to be in company with Mr. Donnet on the afternoon of the day on which he had been engaged in examining and passing the men who had volunteered for this service. He mentioned that he had most explicitly informed them that they were to have "no grog" during the three years that they might expect to be absent, and that there was no objection, nor even murmuring, among them. Mr. Donnet expressed himself as so completely satisfied of the superior efficacy of the abstinence system as regards the endurance of cold, that he fully purposed adopting it himself, and endeavouring to persuade his brother-officers to do the same.

Dr. PATRICK MARTYN, formerly surgeon, R.N., 23 years in the service, examined—Q. 2354. "After the men have endured great fatigue, and perhaps have got very wet, which do you think it would be preferable to give them as a refreshment and comfort, a glass of spirits, or a good dish of hot tea or cocoa?"—A. "I think, looking at it in a medical point of view, that the hot tea would be better for them." Q. 2355. "Do you mean tea particularly, or tea or coffee?"—A. "Tea or coffee. Coffee, perhaps, would be better, being slightly stimulating, and it is not followed by the after-consequence of spirits. There is a depression and collapse in every instance after spirituous stimulants." A. 2372. "I have seen some of the hardest men in the sea-service testotallers, some pilots in North America, for instance." A. 2373. "I recollect in North America having more than once pilots on board in snow-storms, and instances of men on the bowsprit-end for twelve hours at night, and they refused to have grog. I recollect advising some to take it, thinking from their great exposure that they required it, but they took coffee in preference."

Dr. FITZWILLIAM MANSELL, a half-pay surgeon, R.N., 17½ years in the service, examined—This witness states, that in his opinion half the present allowance would suffice for the necessities of any man,—obviously referring to those who have been accustomed all their lives to the stimulus, and thinking that the younger men might go without it with advantage. Q. 2704. "Do you think that in cases of any great exertion, and when they would, according to the practice at present, 'splice the main-brace,' it would be better and more efficacious for the men to have a cup of hot tea or coffee than

a quantity of spirits?"—A. "I think a cup of hot tea or coffee would be more efficacious, and it would enable a man to do more work than the stimulus arising from spirits, which only exists for a certain time. I dare say that a man would be able to go through more physical exertion with tea or coffee,—that is, continuous exertion."

It appears, then, that a very wide experience has now pronounced decidedly in favour of abstinence from spirits when severe and prolonged cold has to be endured; no theoretical considerations having had the least bearing upon the conclusion, which is founded upon the results of the severest trials that could be well devised, carried on through a long period of time. The testimony of Sir John Richardson and Dr. Richard King, readily given to myself, would be confirmed, I am assured, by that of other Arctic voyagers and travellers; and nothing short of the most positive conviction would have induced the Hudson's Bay Company to prohibit the introduction of spirits into their stations, or would have caused the Admiralty to send out the recent Arctic expeditions upon the "temperance" principle.

It must be remembered, that upon this question the *feelings* of the parties concerned are entirely on the side of the indulgence; and it is not likely that, unless strongly urged by their reason, they would ever voluntarily relinquish it. Notwithstanding this, we find the whaling sailors of our own country and of the United States putting their trust, not in grog, but in tea, coffee, and cocoa; and although it may be said that they are forced to do this by the regulations under which they enter, yet it is perfectly clear that such regulations could not have been introduced had they not been acquiesced in by the men. A large number of the best hands now prefer the employ in which "no grog is allowed," and return to it for successive voyages; notwithstanding that the small crews of merchant vessels are compelled to much more severe exertion, and are subjected to much more exposure, than are the far more numerous crews of a ship of war. And even with regard to a temporary exposure to cold and wet, with severe labour,—circumstances under which a stimulus will be best borne, if beneficial at all,—it will have been seen that there is scarcely one of the witnesses, who does not allow that hot tea, coffee, or cocoa, if these beverages can be procured when they are wanted, would be really more serviceable than grog, although the natural liking of the seaman may lead him to prefer the latter. The four medical witnesses all concur in this view.

It is upon such grounds as these, then, and not upon any theoretical assumptions, that I venture to claim for my statement of the incapability of alcoholic liquors to afford the power of continued and severe cold, or any special protection against the effects of cold, wet, and fatigue combined, the value of an established fact. Those who affirm the contrary are bound to disprove the assertions, not only of occasional voyagers and travellers in Arctic regions, but of those whose regular vocation keeps them during a large part of their lives in a temperature far below zero. And, in order to effect this, they must not satisfy themselves with the mere assertions of those who find a glass of grog very comforting to them and feel loath to give it up; but must procure, if possible, the impartial testimony of those who have tried both plans, and who have not any preference in favour of either, save as far as it may serve its purpose best. When they have got a body of evidence adequate to rebut that upon which the Hudson's Bay Company, the Admiralty, 19-20ths of the 700 whale ships of the United States, and a large part of our own mercantile marine, are at present proceeding, it will be time to take up the question afresh. Until then, "universal experience" may be safely affirmed to be on the side of the abstainer.

It may be objected that I have only alluded in this discussion to distilled spirits, and that *they* may be admitted to be useless, or even injurious, without any argument being thence afforded against the use of the less potent fermented drinks, such as wine or beer. To this I have to reply: *first*, that all the data obtainable as to the results of experience, apply simply to the question between spirits on the one side, and tea, coffee, and cocoa on the other. I am not aware that any attempt has been made to test the virtues of wine or beer by comparative experiment. And *secondly*, if alcohol be proved to exert no such power, even in the form in which it is commonly considered the most potent, it seems fair to conclude (at least until the contrary shall have been proved), that the similar virtue ascribed to other alcoholic liquors is equally fallacious, or that, if these liquors really possess it, they owe it to their other ingredients.

It is worthy of remark, that the witnesses of all grades, examined by the Admiralty Committee, agreed in attributing to the present system of spirit-allowances from *three-fourths to nine-tenths* of the offences for which punishments are required on board ship; a large proportion of these offences being committed in a state of absolute drunkenness, and others in a state of irritability which the regular allowance ap-

pears to produce in some men, who never become intoxicated. Surely common sense teaches us that, if a crew cannot be induced to practise moderation in the use of an indulgence, which cannot be shown to have any beneficial effect on him whatever, and is continually disturbing the peace and harmony of the community, such indulgence should be withheld, except upon special occasions. This measure it is obvious that the Admiralty Committee were well inclined to adopt, several distinguished officers having urged it upon them. But it was of course essential for them to consider the practicability of such a change; and it was determined to begin by reducing the present allowance of spirits to one half, leaving it to time to show whether, in the course of a few years longer, the spiritration may not be entirely given up, without that hazard of rendering the good navy-sailor indisposed to serve in his country's ships, which such a step would at present most probably produce.

. Although the evidence adduced by Dr. Carpenter in favour of abstinence from "spirits" when severe and long-continued cold has to be endured is very strong, yet those who, like our reviewer, adopt the views of Liebig on this subject, may not consider it by any means conclusive. By "spirits" we understand gin, rum, brandy, or other liquid containing about fifty per cent of alcohol, to which alone the term "alcoholic liquors" can be with any propriety assigned. The evidence of several of our eminent Arctic travellers, whose opinions are deserving of the highest respect, would, we believe, if submitted to cross-examination, lead to the following conclusions:—1. That injury was done, not by the moderate, but by the immoderate use of strong spirituous liquors; 2. That a moderate use of spirits diluted with water would not be attended with injurious consequences; 3. That coffee, tea, and cocoa, have not yet had a sufficient trial to allow them to be employed universally as substitutes for spirituous liquors; 4. That the recommendation of entire abstinence from spirituous liquors is rather based on the difficulty of restricting their use within moderate bounds, than on any proved injury to the system by their occasional use in a diluted state, and in moderate quantity. The Admiralty evidence, it must be remembered, represents merely the opinions of a few Arctic voyagers: it is the result of an examination in chief; and, had the non-entire-abstinent party been fully represented by learned counsel, it is probable that the cross-examination of the witnesses would have put a very different interpretation, on the whole of the facts.

Before accepting this evidence, therefore, as a complete refutation of Liebig's views, we should be glad to have some facts connected with the *moderate* (not immoderate) use of spirituous liquors in northern regions. Do the Norwegians, or the inhabitants of the northern parts of the Russian empire, find that during the cold season they are as well sustained, in the long run, by the use of coffee, tea, or, in the absence of these luxuries, by *water*, as by the occasional use of spirits, so taken as not to produce intoxication? It would be safer, for the sake of truth, to settle this question by reference to the habits of persons who are born and actually reside in these climates, than by the observations of others born in different countries, and who only occasionally and for comparatively short periods visit the Arctic Regions. The Hudson's Bay Company, the Admiralty, and the Commercial Whaling Companies, are now trying experiments which in some eight or ten years they may have to lay aside. We cannot, therefore, go the length involved in Dr. Carpenter's assertion, that "universal experience is on the side of the *abstainer*." On the contrary, we believe that with properly sifted evidence, with long experience, and by the aid of observations made on individuals constantly inhabiting cold climates, and who know nothing of scientific theories concerning oleaginous and alcoholic fuels in respiration, it will be found that *excessive use* only is prejudicial, and that a *moderate use*, if not an absolute necessity, is certainly not injurious to health. The Hudson's Bay Company have, we believe, an excellent sanitary motive in prohibiting the introduction of spirits into their stations: it has nothing to do with ultra-abstinence principles; but it is intended for the prevention of the mischief arising from excessive indulgence among the inhabitants of their factories, and the Indian tribes around them. If they could so regulate matters that these excesses would not take place, it is our belief that they would be without a shadow of reason for preventing the introduction of spirits, and that the prohibition would cease. The evidence, therefore, in favour of the *total abstainer*, is, in our judgment, neither universal nor wide.

So far as wine or beer is concerned, Dr. Carpenter virtually abandons the question. There is no proof that in *moderation* these liquids are injurious: there is an abundance of proof that under these circumstances they are highly beneficial to health, although like butter, cheese, and some other articles of food, they may not be absolute necessities to the generality of mankind. The varieties of wholesome *beer* contain only from one to three or four per cent of alcohol: they contain grape-sugar, vegetable

matter abounding in nitrogen, with bitter and other principles capable of affording nutriment. To assert that beer is an "alcoholic liquor" because it contains so small a percentage of alcohol, is, it appears to us, a complete misuse of language. We might as reasonably describe the blood as an oily or fatty liquid. It is very well known that the same amount of alcohol taken in water would not act like beer; and there is no proof that the small quantity of alcohol or of its elements contained in beer, acts in any other way than by preserving the liquid from decomposition. If beer be taken in excess, it produces alcoholic poisoning or intoxication: but what article of food is there, either solid or liquid, which can be taken in excess without producing injury to the system? Tea or coffee would be no proper substitute for beer, any more than dripping or train oil would be a proper substitute for butter. Those who could be induced to make the change would probably find that beer and butter were not actual necessities any more than tea, coffee, or train oil. Under these circumstances, we do not perceive why, so long as moderation is observed, the consumer of tea or coffee should not allow the consumer of beer or train oil to follow undisturbed his own taste. We think evidence might be easily adduced to show that the immoderate use of strong tea is decidedly injurious to health, and that tea-totalism is as great a delusion as vegetarianism. But this would have no more influence in inducing us to recommend the prohibition of the use of tea, than the outcry against beer as an "alcoholic liquor" would induce us to prohibit this national beverage which was used in England for at least seven hundred years before tea or coffee was known.

PARACENTESIS IN ACUTE PLEURISY.

DR. HOMANS reported the case which he had recently seen in consultation with Dr. Morrill Wyman, of Cambridge. The patient was a healthy woman, and the operation was done on the twelfth day of the disease. There was great pain, and such urgent dyspnoea that she had been unable for some time to lie down in bed; with enlargement of the side and other physical signs of effusion. An exploring needle having been passed in by Dr. W., about an inch below the left scapula, eighteen ounces of serum were drawn off, but no pus; and with such relief that the patient was able to sleep comfortably that night, in the horizontal position. Two or three days afterwards about half as much more was drawn off, and recovery soon followed. *American Journal of Medical Sciences.*

Medical Intelligence.

SLOW POISONING BY LEAD.

THE subjoined letter, recently addressed by Mr. Herapath, of Bristol, to the Editor of the *Times*, is well calculated to show the subtle nature of lead-poison even when it exists in the very insoluble form of carbonate of lead.

"Sir,—Your number of yesterday, in some remarks upon Dr. Scoffern's patent for purifying sugar by sulphurous acid, left the public in doubt as to what quantity of lead might be taken by human beings without injurious effects. Some time since, in the West of England, a river, the water of which had been used from time immemorial by the inhabitants of a village on its banks without injury, was found to affect their health; symptoms of indigestion abounded, with loss of flesh and appetite; and there were some few cases of colic: they believed that it arose from the use of the river water, as those who used water drawn from a spring at some distance were not so affected. I was requested to analyse the river water, and found in it 1-500,000th part of carbonate of lead, which arose from a mine worked at the distance of three or four miles from the village, on the other side of a range of limestone hills.

"Your paragraph leaves it doubtful whether $1\frac{1}{4}$ grain of lead taken in a week would be injurious. In the case I relate there would be only one grain of lead in nine gallons of water; and yet the health of the neighbourhood was seriously affected.

"I am, Sir, yours respectfully,

"WILLIAM HERAPATH.

"Old Park, Bristol, Sept. 12."

. Allowing that the individuals poisoned by this water consumed as much as a gallon per day, or swallowed in some form or other the lead contained in that quantity of water, it follows that they would have taken no more than about *three-quarters of a grain* of lead per week! This infinitesimal quantity, according to Mr. Herapath, was quite sufficient to endanger health. An observation of this kind clearly shows that we are not able to set a limit to the proportion of lead in an article of food consumed daily, which will be inert or free from consequences injurious to health. If one *half-millionth part* of insoluble carbonate of lead may thus affect health, it is quite within the range of probability that this or a larger proportion of sulphite, or any other insoluble salt of lead, taken daily in sugar, treacle, or any article of food, may prove equally injurious. In

reference to the sugar-refining question, Dr. Gregory asserts that the highly *insoluble* carbonate of lead is the *truly poisonous* lead-compound; while he says it might be predicted of the sulphite of lead that it is as harmless as chalk, *because of its excessive insolubility*. This is an ingenious way of dealing with chemical doctrines. Either insolubility (in water) has nothing to do with the question of poisoning, or the carbonate of lead should be just as harmless as chalk,—an assumption which is contradicted by daily experience. It may be said that 500,000 parts of water will dissolve one part of carbonate of lead: this is highly probable; and, as insolubility is only a relative term, it is equally probable that this, or even a much smaller quantity of water, would dissolve one part of the sulphite of lead. The "excessively insoluble" sulphate of barytes is dissolved by 40,000 parts of water. It must be remembered, however, that the secretions of the stomach differ from water. They contain organic matters, acids, and salts, which act upon mineral substances in a way which chemical experiments on the solvent powers of water would fail to explain. Mr. Herapath has done good service by showing how minute a quantity of lead will affect human health; since facts of this kind will prevent a general trial of lead-refined sugar with the serious risk of endangering the health of the population.

MEDICAL SUPERNUMERARIES AT FORT PITT.

A CORRESPONDENT of the daily journals gives the following unpromising account of the occupations and prospects of young military surgeons stationed at Fort Pitt, Chatham:—"The supernumeraries," he says, "consist of a fluctuating number of young gentlemen fully educated as medical men, many of them possessing University degrees, and all having passed, in addition to the ordinary professional ordeals, the Army Medical Board examination. These, having through the influence of friends, or as a reward of merit from certain colleges and universities, received Sir J. M'Gregor's recommendation for a medical commission in the army, are ordered to Chatham to do duty at Fort Pitt for two or three months until a vacancy occurs, and are informed that meanwhile they must lodge and maintain themselves. They report themselves to the principal medical officer, take lodgings near the Fort, are subjected to military discipline, and confined within the walls of Fort Pitt (often with severe hospital duty) daily from 9 A.M. until 1 P.M., and occasionally until 5 P.M. They are compelled to join an expensive mess, and to subscribe to the medical library and to a fund for officers' widows. In return the four seniors (called

acting-assistants) receive 5s. *per diem*, and the rest, to the number of ten or twelve, nothing. Their sojourn at Fort Pitt is frequently eight, ten months, or even longer, instead of two or three; and accordingly it sometimes happens that one of these unfortunates, having with difficulty secured what he was led to consider a sufficient fund to enable him to take his commission, is compelled to expend so much while waiting for it that he is obliged to throw up his claim, and to retire with the comfortable reflection that he has given one of the best years of his life, and wasted enough money to have started him in a private practice, not to speak of the actual hand and head work which has thus been exacted without remuneration, and which is very often exceedingly severe, and to a fully qualified medical man somewhat degrading also."

THE CHOLERA IN ALGIERS.

ACCOUNTS from Algeria state that the cholera had ceased at Bona, and broken out at Biscara, where it attacked dogs, fowls, and other animals, with the same violence as human beings. Several officers of distinction, amongst whom is the commandant of Biscara, have fallen victims to the malady. It was, however, believed that the period of its disappearance was near at hand.

MORTALITY OF NEW YORK IN 1849.

THE visitation of epidemic cholera, during the last year, has given an appalling increase of the deaths occurring in 1849, the aggregate being 23,773, which is more than 5 per cent of the population, estimating the latter at 450,000, which is not far from the truth. The average mortality of the city for the last ten years, prior to 1849, was not more than $\frac{1}{4}$ per cent.; so that it has more than doubled during the past year. That the increase is mainly to be ascribed to the direct and indirect effects of the epidemic is scarcely susceptible of doubt. For, although only 5,071 of the deaths are set down as cholera cases, yet several thousand more were the undoubted victims of the epidemic atmosphere equally with these, although reported among the interments as diarrhoea, dysentery, cholera infantum, and cholera morbus! by those who falsely claimed to cure the cholera, and thus concealed the cases they lost, under other names.

FEE'S PAID TO THE MEDICAL ATTENDANTS OF THE LATE SIR ROBERT PEEL.

AN evening paper states that the executors of the late Sir R. Peel have, within the last few days, remitted fees to the various medical gentlemen who attended him, and endeavoured to alleviate the effects of the fearful accident which was the means of

terminating his life:—To Sir Benjamin Brodie, Bart., 250 guineas; to Alexander Shaw, Esq., 100 guineas; and to the other gentlemen proportionate sums.

EXPENSES OF PUBLIC BOARDS.

A PARLIAMENTARY paper has just been printed, showing in detail the expenses of the General Board of Health, the Commissioners in Lunacy, and the Poor Law Board. The expenses of the General Board of Health to the 31st of March last were £3,084. 6s. 2½d. The travelling and personal expenses of the Commissioners in Lunacy, in the year ending the 31st of July, were £2,355. 11s. 11d.; and of the Poor Law Board, for the year ending the 31st of March last, £2,878. 0s. 2d.: leaving a surplus of £1,261. 19s. 10d. For the General Board of Health £8,000 were voted; for the Commissioners in Lunacy the exact sum; and for the Poor Law Board £10,000.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 12th September, 1850:—William Smith Scholefield, Lartingham—Benjamin Mallan—Thomas Wheeler, Ulverstone—William Browne—Thomas Johnson, Weymouth.

OBITUARY.

PROFESSOR MARCHAND.

WE have to announce the death of Professor Marchand, which lately took place at Berlin from an attack of cholera. The deceased was the discoverer of some useful tests in pharmaceutical chemistry and toxicology.

MR. THOMAS DAVIS, ESQ.

On the 25th ult., at Hampstead, Middlesex, aged 73, Mr. Thomas Davis, surgeon.

ALEXANDER TAYLER, ESQ.

On the 7th inst., at Queenstown, Ireland, Alexander Tayler, Esq., for sixty-six years surgeon in the Royal Navy.

JOSEPH NEVILLE, ESQ.

On Thursday, the 12th inst., at Croydon, after a protracted illness, Joseph Neville, Esq., surgeon.

CASE OF RECOVERY FROM THE PASSAGE OF AN IRON BAR THROUGH THE HEAD. BY HENRY J. BIGELOW, M.D., PROFESSOR OF SURGERY IN HARVARD UNIVERSITY.

THE accident occurred upon the line of the Rutland and Burlington Railroad, on the

18th of September, 1848. The subject of it, Phineas P. Gage, is of middle stature, twenty-years of age, shrewd and intelligent. According to his own statement, he was charging with powder a hole drilled in a rock, for the purpose of blasting. It appears that it is customary in filling the hole to cover the powder with sand. In this case, the charge having been adjusted, Mr. Gage directed his assistant to pour in the sand; and at the intervals of a few seconds, his head being averted, and supposing the sand to have been properly placed, he dropped the head of the iron as usual upon the charge, to consolidate or "tamp it in." The assistant had failed to obey the order, and the iron striking fire upon the rock, the uncovered powder was ignited and the explosion took place. Mr. Gage was at this time standing above the hole, leaning forward, with his face slightly averted; and the bar of iron was projected directly upwards in a line of its axis, passing completely through his head high into the air. The wound thus received was oblique, traversing the cranium in a straight line from the angle of the lower jaw on one side to the centre of the frontal bone above, near the sagittal suture, where the missile emerged; and the iron thus forcibly thrown into the air was picked up at a distance of some rods from the patient, smeared with brains and blood.

From this extraordinary lesion, the patient has quite recovered in his faculties of body and mind, with the loss only of the sight of the injured eye.

The iron which thus traversed the skull weighs thirteen and a quarter pounds. It is three feet seven inches in length, and one and a quarter inches in diameter. The end which entered first is pointed; the taper being seven inches long, and the diameter of the point one quarter of an inch; circumstances to which the patient perhaps owes his life. The iron is unlike any other, and was made by a neighbouring blacksmith to please the fancy of the owner.

Dr. Harlow, in the graphic accounts above alluded to, states, "immediately after the explosion the patient was thrown upon his back, and gave a few convulsive motions of the extremities, but spoke in a few minutes. His men (with whom he was a great favourite) took him in their arms and carried him to the road, only a few rods distant, and sat him into an ox cart, in which he rode, sitting erect, full three quarters of a mile, to the hotel of Mr. Joseph Adams, in this village. He got out of the cart himself, and with a little assistance walked up along flight of stairs into the hall, where he was dressed.—*American Journal of the Medical Sciences*, July 1850.

11. Premature Birth	20
12. Old Age	24
13. Sudden Deaths.....	20
14. Violence, Privation, Cold, &c....	51

The following is a selection of the numbers of Deaths from the most important special causes:

Small-pox.....	7	Convulsions.....	33
Measles.....	15	Bronchitis.....	38
Scarlatina.....	38	Pneumonia.....	40
Hoping-cough.....	20	Phthisis.....	117
Diarrhoea.....	78	Lungs.....	5
Cholera.....	4	Teething.....	10
Typhus.....	47	Stomach.....	1
Dropsy.....	17	Liver.....	4
Hydrocephalus.....	26	Childbirth.....	4
Apoplexy.....	33	Uterus.....	4
Paralysis.....	17		

REMARKS.—The total number of deaths was 64 below the average mortality of the 37th week of ten previous years.

NOTICES TO CORRESPONDENTS.

The letter on the Testimonial to Dr. Conolly shall appear in the following number.

We regret that our space is so occupied that we cannot this week find room for the report of the Committee of the National Institute, or for various papers which are in type.

Dr. Blacke's work on Asiatic Cholera has reached us. It shall be noticed in an early number.

The following papers have been received, and will have early insertion:—Mr. Noble on the Contagion of Cholera; Mr. Kingdon's case of Sloughing of Malignant Tumor; and the King's College Hospital Report.

Lectures.

LECTURES

ON THE

MEDICAL JURISPRUDENCE OF
INSANITY.

*Delivered in the Medical School of King's
College, Aberdeen.*

BY ROBERT JAMIESON, M.D.

Lecturer on Medical Jurisprudence in the
University.

LECTURE V.

*General description of the insane state
(continued)—(c) Insane impulses—(1)
The suicidal impulse—Suicide amongst
the insane—Its Lunatic characteristics—
Medico-legal consideration of suicide—
Felo-de-se—legal consequences—Self-
murder, insane suicide, and suicidal
moral insanity—Circumstances of these
contrasted—Suicide from suggestive op-
portunity, fascination, imitation, &c.—
When is suicide to be deemed an act of
insanity?—Legislation on the subject of
suicide—(2) The homicidal impulse—
Medico-legal consideration of homicide—
Insane homicide and homicidal moral in-
sanity—Reil's description of a paroxysm
of mania without delirium—Delirium
in agendo—Criminal homicide and in-
sane impulse contrasted—When is homi-
cide to be deemed an act of insanity?—
Connected delusion—Contemporaneous
delusion—Consecutive delusion—Moral
insanity.*

THE extravagant conduct evidentiary of intellectual disorder which we have just been considering does not unfortunately comprehend all the diseased actions that lunatics commit. We have yet to speak of those which do not arise out of delusion solely, but are rather the exponents of the diseased will than of deranged understanding. Insanity is not in every instance want of wisdom merely, but often want of virtue also; it may have the aspect of crime as well as that of folly. When the former predominates, the medico-legal difficulties are great. Lunatics are subject to a variety of *diseased impulses*. This is not merely a medical assumption, but a fact proved by the nature of the actions to which they lead, and the testimony of those who have experienced them. There are no psychological nor physiological grounds for denying that these morbid propensities may be the sole indication of mental disease, and the doctrine is upheld by the testimony of many who have felt its truth, and is ad-

mitted by all who have had opportunities of studying the pathology of the mind. When such diseased impulses appear to be uncombined with delirium, they form varieties of what is termed "moral insanity"—that species of insanity (called partial) in which the outward exhibition of the disease is limited to the emotional faculties and the power of self-control.

The suicidal impulse.—The lunatic propensity to self-destruction is the one which we shall first discuss: it is the most common, and certainly not the least curious. The homicidal impulse is only a diseased manifestation of the destructive power, and of the natural inclination to revenge—of tendencies counteracted by moral considerations only; so with kleptomania—so with dipsomania: but self-destruction is a defiance of the strongest instinct of our nature, and, if sanely executed, the extremest assertion of personal freedom.

Amongst the insane, suicide is most frequent in those labouring under monomania with depression, but it may occur as a consequence of any of the forms of insanity. I have known it to be committed by one labouring under extreme and long-standing dementia, in whom there had never been the slightest grounds for suspecting such a desire. In a thousand lunatics the suicidal inclination was clearly developed in a hundred; and of these, five succeeded in effecting their object. It may be the result of delirium, or false perception; of delusion, of sudden impulse, of insane reasoning, of suggestive opportunity, and of example. It is chiefly to be dreaded in those lunatics who are fond of solitude, and who are the subjects of melancholy, insane terrors, and religious delusions.

The suicidal propensity of the insane has morbid features in addition to the disease manifested in the impulse. There are inconsistencies in the desire, and peculiarities in the modes of its accomplishment. The hypochondriac believes that he is dying of an incurable malady, and is miserable because he is dying; yet he seeks, nevertheless, to terminate his own existence: a monomaniac, fearful of everlasting torments, eagerly seeks to anticipate them with violent hands: another, fearful of the gallows, bends every thought to compass a noose for himself in some unseen corner, apart from those that watch him: and a lunatic who believes that he is already dead, and in the other world, is not by any means to be entrusted with a knife. The delusion of an insane person impels him towards suicide, but often it is suicide in a particular way. He is fascinated, say, by the notion of hanging himself, and requires much care to prevent his design; but, if he is successfully thwarted in this, he may

often be trusted with other means of injuring himself. The person who is on such an account compelled to sleep in a bare apartment, whose walls do not exhibit the temptation of a single peg or projection, upon a low bed without posts or curtains, and whose framework is tightly screwed to the floor, may be perhaps allowed with safety to eat his meals with knife and fork, and to enjoy other liberties and comforts which must be denied to others whose suicidal taste is of a different description. In the same way, a lunatic may go on contriving how he shall find an opportunity to cut his throat, to the neglect of all means that may present themselves for hanging himself by the neck. Modes of death are chosen of a kind unknown unless in the history of insane suicide: for example, suicide by starvation is not unfrequent among the insane, but scarcely ever attempted, or if attempted, never persevered in from preference by any person of sound mind. I should perhaps except the case of Pomponius Atticus, the friend of Cicero; but it is not unlikely that his painful disorder had affected his mind: at all events, he was in such a condition as to die on the fifth day, and therefore his perseverance was not brought to an extreme trial. Even amongst prisoners condemned to death the attempt is uncommon, and success in it almost unknown. Amongst the insane it is otherwise. I have myself known of more than one instance. Sometimes, in obedience to a delusion, it is had recourse to from choice, but more frequently it is the last resource of a lunatic thwarted in other modes of self-destruction. The attempt may be combated in many ways, and is usually overcome; but, if the insane resolution fail not—and the insane will is sometimes unconquerable—a certain and a fearful tragedy has begun. The propensity is treated as a disease, but the subject of it resists physic. Leeches are applied to the head, a blister to the neck—something is done to the epigastrium: he is left alone with food—he is tempted with delicacies—he is encouraged to drink—he is promised all things: but he holds out, and emaciates hourly. Food is introduced into the stomach by a tube passed into the œsophagus by the mouth or nostrils: he resists with all his might; and, if unsuccessful, attempts to excite himself to vomiting. He is placed under the influence of chloroform, perhaps, but becomes only insensible, not compliant: he is violently fed daily, but is evidently gaining the victory. The struggle becomes dangerous by the exhaustion itself induces. Nourishing enemata are resisted and expelled; and, some day, when raised up, he suddenly falls back and dies of syncope. In a well-conducted asylum, starva-

tion is almost the only possible mode of suicide. In those sound of mind it is nearly an impossible kind of self-murder.

Medico-legal consideration of suicide.

Suicide is a crime in law—a fact not of a sort to be of necessity presumed. It is, it seems, the crime of *felo-de-se*—a phrase of dubious latinity, understood to indicate self-murderer. Of the moral guilt there can be no doubt; but there are many unchristian offences of which legislation makes no account, which it would be more rational to recognise, both for the weight of example, and on the principle of punishing: for those who are bent on self-destruction on any other grounds than a hysterical impulse of imitation, are incapacitated to profit by application of the example, and remove themselves from the influence of human inflictions; the worst is already looked upon and encountered; nothing can harm them more. The goods of a *felo-de-se*—that is, his own personal and moveable property—are forfeited to the Crown, and his will in relation to them is invalid. Formerly, the body having been further mangled by being transfixed with a stake, was buried dishonourably under the highway. Having disgraced his body and robbed his children, the law entitled the wife to her dower, and permitted the real estate to descend to his heirs, or fall to any to whom it was bequeathed. Suicide is not evidence of insanity. The mere fact of a testator making away with his life, although immediately after the execution of his will, is not deemed sufficient ground for setting aside the testament, in so far as the crime of his death permits it to be valid. If an individual commits murder, and thereupon attempts self-destruction, this will in no way affect his legal responsibility. Still further, if an individual in attempting suicide injured another, the mere fact of suicidal intention would afford no plea against trial for homicide. Thus, if a person bent on self-destruction turned a loaded pistol to his head, but from nervous agitation, or some other cause, missed his mark, and shot some one behind him, the suicidal aim would not free him from the charge of blood-guiltiness. One attempting death by drowning has been found liable for the accidental death of an individual who jumped into the water to save him.

We shall distinguish three kinds of suicide—viz., self-murder, insane suicide, and suicidal moral insanity.

Self-murder is that voluntary rational suicide which is implied in the technical phraseology of *felo de se*. Suicide is not always insanity; it occurs under circumstances which do not indicate incapacitated

judgment or diseased will. It may be the sinful result, in an unchristian mind, of a vigorous comparison betwixt long-continued mental distress and transient physical pain, betwixt one mode of violent death and another, between present actual wretchedness and a doubtful condition of future existence. It may be evil done that good may come: thus Leonidas volunteered the required loss of Heracleidan blood at Thermopylæ; Marcus Curtius leaped into the chasm; the citizens of Calais offered themselves for the gallows: and the virgin may prefer suicide to certain dishonour. In some countries suicide has been in certain circumstances a religious duty or a customary etiquette. The Japanese dignitary rips up his abdomen when disgraced from office; the concubines of the Peruvian Inca sacrificed themselves on his tomb; and the Hindoo widow immolates herself on the funeral fire. Self-murder is, however, I believe, the rarest form of suicide. It is to be presumed to be a sane act, in the absence of contrary evidence, when such motives as the above are clearly traceable; but even then, when it is the deed of remorse or despair, it is the result of a condition as uncontrollable by the judgment as a diseased impulse. Suicide, preceded by revengeful murder, following intelligible motives, implies *felo de se*. The less painful and the more gradual the mode of death selected, the greater would be the presumption of sanity. Death by poison, charcoal vapour, or chloroform, would less indicate a diseased impulse than would pistolling, cutting the throat, or precipitation. The presumption of insanity would also be weakened by the fact of self-destruction being the result of a community of resolution; as when the member of a suicide club, if such a society exist, is no more to be seen, or the crew of a boarded ship blow themselves and the enemy into the air, or the daughters of a Lord Archibald plunge together into the lake. The conjunct suicide of two individuals only, especially of the opposite sex, may, however, be a conjunction of insanity with a diseased intensity of sympathetic emotion.

Insane suicide is the phenomenon of self-destruction occurring amongst those labouring under any of the forms of insanity, as already spoken of, and on which it is unnecessary to dilate. The deed is to be held as resulting from the mental disease in all cases in which it is committed by a lunatic, whether it can be seen to be attributable to the influence of disordered judgment or not; for we can neither trace all the diseased motives which govern the conduct of the insane, nor, as we have already seen, reconcile their actions with the objects which

impelled them. There is no rationale in the doings of lunacy.

Suicidal moral insanity.—The cases of self-destruction which we are to consider as belonging to this class differ from what I have termed self-murder in being associated with symptoms of loss of control, and from insane suicide in being uncombined with manifest disease of the understanding. The suicidal propensity is, in some instances, a form of insanity per se, a variety of moral insanity, and unaccompanied by incapacity of judgment; in other cases it only appears to be so, the intellectual disorder being either undisplayed or overlooked. The simplest example of pure suicidal impulse, uncomplicated with disordered judgment,—suicide from loss of control,—is the self-destruction which may be the result of *fascination*,—the feeling whose approach some of you possibly may have experienced in your own person in looking over a precipitous height. The natural,—that is to say, the healthy, impulse in such a position would be an excitement of the instinct of self-preservation; the opposed feeling, though perhaps common, is truly abnormal, and has, it is probable, a pathological source, and may be allied to that feeling of vertigo which is still more common in such a situation. This last is said to be a sensation developed only in the special circumstance of an immediate tangible connection with the point towards which the eye is directed: it is felt in looking from a precipice, but not from the car of a balloon: and a similar sensation attends looking up the face of a perpendicular cliff, or to the high roof in the interior of a cathedral, but does not interfere with one gazing on the sky. It would be interesting could it be known whether the suicidal impulse is ever developed by looking downward from a balloon. It may be said generally of suicide from suggestive opportunity, that it is a morbid phenomenon. It is the most producible of all the insane impulses. Were a convenient noose to be hung up in the sleeping apartments of a lunatic asylum, doubtless more than those who went to bed suicidally inclined would be found suspended in the morning. It is not so discreditably to the country that the gallery of the Monument was found necessary to be encaged, as that it was not so protected before that necessity was proved! Suicide from *imitation* is another kind of self-destruction consequent on diseased impulses without deranged intellect, although it has been proved capable of being prevented by disgracing the dead body. The Roman senate finding it necessary on one occasion to attempt the check of a suicidal epidemic amongst the fe-

males, succeeded by decreeing the exposure of the suicide's body naked in the public highway; and we are told by Dr. Burrows that the practice of suicide at one time, in a British regiment in Malta, was put a stop to by dragging the naked corpse on a hurdle ignominiously before the whole band, and throwing it into the fosse: but these efforts are no proof that the impulse was not a diseased one; true, self-murder could not be hindered by such means. "The morbid impulse is fettered not by the unaided free will of the individual, but by a strong mental impression tending to arouse the will to free action. Insanity, it has been said, may be prevented or controlled by voluntary exertion; but it will neither be the one nor the other without the agency of external stimulation; unless in the earliest steps of its progress, or the stages of its retrogression." The suicidal inclination is frequently a persistent suggestion rather than a sudden impulse; but is in such cases also a pathological symptom. Our natural instincts, even the strongest, may, in obedience to the higher motives that influence the mind, such as a sense of duty and religious obligation, be successfully resisted; but the annihilation of these instincts, and impulses *contra naturam*, are in every instance to be looked upon as morbid. The desire to terminate life is a psychical reflex of physical disease. "It may be laid down as an indisputable axiom," says one who has thought, written, and seen much of this state (Dr. Winslow), "that in every case of this kind bodily disease may on a careful examination be detected. We never yet saw a case where a desire to commit suicide was present in which there was not corporeal indisposition." In all the foregoing examples of what we have termed suicidal moral insanity the intellect is understood to be sound; but there are others in which this is at least problematical. In many instances, doubtless, the intellectual complication is concealed or overlooked; in others the deed has been the first and last act of the disordered judgment. The attempt at self-destruction is frequently the antecedent of insanity,—the main indication of that premonitory moral disorder to which I have alluded.

When is suicide to be considered as the act of insanity?—In answering this question you are to keep in view that in the word insanity are comprehended the five varieties of the disorder formerly discussed, one of which, moral insanity, is not yet recognised in law. You are to take into account the history of the individual, the mode in which the action was committed, and the condition of the body. Self-destruction ought to be held as insanity when it is the

deed of one hereditarily predisposed to mental disease, or to death by suicide, particularly if the predisposition is inherited from the parent of the same sex, as this gives increased force to congenital tendencies. Dr. Gall, Dr. Burrows, and other writers, have given striking examples of suicide occurring in three or four consecutive generations of a family, the result undoubtedly of inherited qualities, and not to be accounted for on the mere ground of suggestive example and vicious imitation. Self-destruction is to be deemed insanity also in all those cases in which the circumstances of the individual were not such as to develop any of those motives to which allusion was made in speaking of self-murder or *felo de se*; so likewise in every instance in which it is to be ascribed to mere imitation, or to the fascination of suggestive opportunity. The mode of committing the action may itself be indicative of disease. If little could be inferred from the single fact of a person hanging, drowning, poisoning, or pistolling himself, there could certainly be no doubt of the state of mind of one who chose rather to throw himself into a furnace, to starve himself to death, to crucify himself, or to kill himself by cutting off his genitals. I would also hold it as sufficient ground for a similar conclusion where it appeared, as formerly described, that the individual had not so much the desire of self-destruction as that of dying in a particular way; where, for example, he did not seem to wish to kill himself so much as to hang himself. Suicide amounts to proof of insanity when committed by people labouring under certain diseases: as pellagra,—an endemic skin disease in Lombardy, which, according to Professor Tomassini, and other Italian physicians, occasions often an irresistible impulse to self-annihilation,—hypochondriasis, paralysis, hysteria, epilepsy, extreme bodily pain, uterine derangement, spermatorrhoea, nostalgia, intoxication, &c., all of which are efficient causes of mental diseases, and many of them states which are either transitional to, or premonitory of, insanity. Any of those pathological appearances which are more peculiarly connected with mental alienation if found in the body of a suicide, ought to lead us to the inference that the individual laboured under mental disease; and indeed, in the present state of our knowledge, if we can distinctly make out that he suffered from bad health, the violent death should be ascribed to sympathetic cerebral disturbance. In short, suicide is presumptive of insanity, and ought to be held probative in every case in which the recognised causes of *self-murder* were not clearly present.

Self-murder is the rarest form of suicide; and doubtless many cases of supposed felonies are examples of obedience to some morbid impulse; all other suicides are probative of unsoundness of mind. Juries have been often twitted with the commonness of the verdict of "temporary insanity" in cases of self-destruction; but they are in the main right in their conduct and dealing with the matter in the spirit that is most philosophical. The practice of the law is, on the other hand, chargeable with being harsh and unenlightened. The attempt "to put down suicide," unless in the way of preventing its causes, is absurd in the extreme, when the deed is not the consequence of epidemic imitation; for the act is an unnatural one beyond the domain of legislation. The man bent upon death, whom social affections, conservative instinct, and religious principle do not sway, is beyond the influence of example and authority. He has reached an acme of misery not to be rendered more miserable by the prospect of post-obit vengeance, nor to be deterred from its morbid will by legal consequences often but ill understood, and in a multitude of cases impotent and inconsequential; and he appeals his case to a tribunal higher than all the united estates of humanity. Legislation should go no further than this: for the protection of heirs (not their robbery), to vitiate the will of a suicide when it is contrary to the legal order of succession; and for the protection of the public, to hold the intention of suicide when accidentally productive of death to others to be punishable as homicide, unless where insanity can be clearly established, in which case the individual should be confined for life.

The homicidal impulse.—The manifestation of this propensity is much more rare among the insane than the suicidal impulse is. The desire to kill was a feature more or less abiding in about 1 per cent. of the cases treated in the Aberdeen Lunatic Asylum. The insane may commit homicide under the influence of delusion, delirium, imbecility, where there is imperfect appreciation of consequences, or simply as a result of the moral perversion which accompanies the disease. The propensity is rather more common in the insanity of females than of males; it is most usually combined with epileptic mania.

Homicidal moral insanity may be employed as the term to designate those cases in which a morbid impulse to kill is the sole indication of diseased mind. Though much less common, this is a form of mental disorder as veritable as the suicidal moral insanity of which we have spoken; it is admitted by all recent writers, and has been

recognised in criminal courts. The propensity has been found combined with the conditions of menstruation, pregnancy, parturition, uterine derangement, gastric disorder, cerebral congestion, epilepsy, and hypertrophy of the heart, and may be persistent, intermittent, or occasional. These conditions are to be looked upon as predisposing physical causes; there may be also predisposing moral causes at work,—as, for example, grief and despondency; but the deed flows immediately from some mental impression by a morbid action so powerfully exciting the homicidal idea, as to give it an instinctive force, leading to an action which is irresistible,—independent of the will. The deed may be the result of imitation, the idea induced by murderous narratives, or suggested by the sight of lethal weapons, or by the exposed and defenceless condition of the victim. When the psycho-physical relation is once disturbed, whether by the influence of corporeal or of mental agencies depressing the vitality, and the predisposition to diseased manifestations thus induced, ordinary influences become exciting causes of extraordinary conduct. I have already said that mental impressions, often of a common kind, are the originators of delusion (incapacitated judgment); so are they also of irresistible impulses (incapacitated will). In the former case extravagant conduct results mediately from the delusion excited; in the latter it results immediately from the mental impression, which, being an emotional one, manifests itself in action without any intervention of intellectual disorder. The homicidal impulse, and the insane impulses in general, constitute, therefore, the simplest and most completely objective form of madness. Reil adopts the same view. He considers them to be forms of mania, and to be mania without any extraneous addition. He appears, in the following description of the paroxysm, to assimilate its phenomena to those of epilepsy. "The paroxysm," says he (I read from Feuchtersleben's *Psychology*), "generally begins with all kinds of corporeal phenomena: a pressure exists at the pit of the stomach; shuddering through the whole body (often commencing at the spine); the tongue is loaded; there is a sensation of burning heat in the bowels; great thirst and constipation: the heat rises upwards to the chest, neck, and head; this last aches; there is a singing and buzzing in the ears; the look becomes anxious: the patient says that the heat rises before his eyes; he often warns those about him, and entreats to be prevented from doing mischief; the countenance becomes flushed; the arteries of the neck and temples throb

violently: at length the excitement extends to the brain; and at this moment arises the blind irresistible impulse to murder, commit suicide, theft, arson, or some other outrageous act; just as epilepsy ensues when its preliminary *aura* has reached the brain. These somatic (corporeal) symptoms are, however, often wanting. The disease is permanent, though mostly periodical.*

In homicidal moral insanity there is no discoverable intellectual disorder antecedent or subsequent to the act. Several writers maintain, however, that there is disordered perception or delirium during the time that the deed is done. In such a paroxysm as that vividly described by Reil one would infer delirium in the climax. Without insisting on this feature in every case, I believe that very frequently the patient may not have a competent knowledge of circumstances at the time.

I shall not take up your time quoting examples of this variety of insanity, leaving it to yourselves to study the many cases which you will find recorded in medico-legal works. I have often seen the homicidal desire as a feature of derangement, but have met with only one or two instances; and these not of a striking kind, in which the impulse itself formed the sole mental disease. In one of these cases the subject was a young woman, of a good and cheerful disposition naturally, who acted as a servant to an invalid lady. Her health got disordered from the nature of the duties which she had to discharge. She lived in the most solitary way, was very rarely indeed out of doors, and had to submit to perpetual night watching, and the constant peevishness and selfish exactions of an invalid. Such were the predisposing causes of the malady. The propensity was engendered by reading to her mistress, night after night, from newspapers, details of those monstrosities of crime which are so usually to be found in their columns. She was at length seized with a morbid desire to strangle her mistress as she lay asleep. The impulse grew stronger and stronger, and feeling that it would become irresistible, she determined to save herself by flight. She left her situation, and, at her earnest solicitation, to be protected

from the consequences of her actions, was lodged in an asylum. This patient had not the melancholic temperament which is common in such cases, had no hysterical tendencies, but was robust, of a sanguine habit, cheerful, and well inclined. There was no disorder in the uterine functions; the only distinct symptoms of disease were gastric, accompanied with headache and restlessness at night. When removed to the hospital there was no manifestation of mental affection, save depression of spirits; and when her disordered health was rectified she was discharged, and has ever since kept well.

Homicide from insane impulse differs from murder, in being a diseased act, suddenly committed in blind obedience to an instinctive impulse, or to a desire which has gradually become irresistible. None of the ordinary motives of crime are discoverable: there was no antecedent enmity or quarrel, and there is no resulting advantage. The objects sacrificed are most likely either previously unknown to the patient and accidentally encountered, or they are those, as his wife and children, whom he has always regarded with the deepest affection. The act is one indicative of much mental and physical excitement; it is not slow-poisoning secretly carried out, but a bloody deed savagely done; there is probably not one wound, but many; not one ghastly corpse, but several. When the slaughter has satiated the desire, there is either terror and flight, grief and confession, or remorse and suicide; but as frequently no relief seems to follow the indulged impulse; in which case there is neither attempted concealment, surrender to justice, denial, nor remorse. There will often be evident physical disease, with indications of moral insanity, or perhaps even of approaching or overlooked intellectual disorder. None of the circumstances of the action necessarily indicate insanity; the most characteristic of them are of occasional occurrence in criminal homicide. The absence of all motive is presumptive, but is with difficulty distinguished from concealment of motive; and the dependence of the impulse on disease, with its independence of the will, may be indicated in the history of the homicide and his crime, but cannot be indubitably proved.

When ought homicide to be considered as the act of insanity?—In speaking of self-destruction, I stated that the act by itself is to be held as presumptive of insanity; but in regard to homicide the presumption is much more on the side of crime than of disease; the former runs contrary to natural instincts, whereas the latter results from normal impulses which the divine commandment indicates have to be re-

* In a case of insane impulse (suicidal and homicidal) which I lately saw with Dr. Christie, of Aberdeen, the existence of our *aura* as described by Reil was well marked. The strange feeling, described by the patient as a "heat," began in the lower extremities, progressing gradually upwards to the head. The impulse was not manifested merely when the paroxysm reached its height, but commenced at the same time with the *aura*, which produced an intense feeling of restlessness and wretchedness when at its climax.

strained. Every one has the capacity to kill in self-defence; but there are many whom the instinct of self-preservation would, in all circumstances, keep from self-destruction. Homicide is not to be held as a criminal action when it is committed by one labouring under any form of delirium, the consequence of disease, or naturally of such an imbecile condition as to have an imperfect knowledge of right and wrong, and an imperfect appreciation of consequences. It ought to be considered as an act of insanity when it flows directly from a delusion which overrides the judgment and directs the conduct; indeed, in every case in which insane delusions exist, the presumption is strong that the deed is an act of insanity, whether it can be directly traced to the impulse of delusion or not; for, as already insisted upon, the consequences of a delusion are not to be foreseen. When outrageous or extravagant conduct co-exists with delusion, they are probably connected with each other, although the relation may not be apparent. Homicide without any of the usual motives of murder ought to be esteemed an act of insanity when it is followed by evident derangement of mind; for the deed has, in such a case, it is to be presumed, been the consequence of the moral perversion, which you are aware is so often the initial symptom of lunacy. In cases in which no intellectual derangement is obvious, the action is still to be attributed to insanity when it appears to have been motiveless, the manifestation of a blind irresistible impulse, inconsistent with the natural tendencies of the individual, and indicating in its circumstances the temporary existence of delirious loss of control; when it is also the act of an individual labouring under some of those diseased states which are frequently associated with insanity, as cause, complication, or consequence,—who has a hereditary predisposition to disease of the mind, or who has at some former period actually been afflicted with the malady.

ON PARALYSIS OF THE SIXTH PAIR OF NERVES. BY M. E. L. EMILE BALIN D'HURTEBISE.

THE tuber annulare is the ordinary seat of lesion in paralysis of the sixth pair of nerves: in one case it may extend to the pyramidal bodies, in another it may reach the nerve itself.

The small extent of the origin, and consequently of the relations of the roots of the sixth pair, accounts for the comparative rarity of their affection.

The nerve may become the seat of disease in its course, but it is more frequently

affected by morbid conditions of parts with which it becomes related in its course—*e. g.* varicose ophthalmic veins, or aneurism of the artery, or disease of the bone.

Paralysis of the sixth pair is seldom the result of cold, or of lead-poisoning, and is in any case rarely met with except as complicated with paralysis of the third pair. It occurs more frequently on the left than on the right side, and in men more than in women. It is also common at the adult age.

The symptoms will vary according as the paralysis is simple, or complicated with paralysis of other nerves.

In simple cases two orders of phenomena are observed—the inward deviation of the eye, and impairment of vision. The inward deviation is constant, but may be more or less distinct; sometimes the whole of the cornea, sometimes only a portion thereof, disappearing at the inner angle of the orbit. The globe may be moved upwards or downwards, but not outwards. This condition remains the same if the eye be forcibly closed. The impairment of sight, with double vision, is also constant, and among the earliest symptoms. Objects are seen confusedly as well as double. If the sound eye be closed, one object will be perceived, but only indistinctly. When seen double, if the objects be superposed in vision, the lower is the image of the real object. When the double images are side by side, as when placed vertically, the image to the right side is the image of the real object when the left eye is affected, and *vice versa*. The impairment of vision is in all cases proportionate to the strabismus.

Complicated cases.—The accompanying paralysis of the third pair is seen in the falling of the upper lid, the dilatation and immobility of the pupil, the immobility and a certain amount of protrusion of the globe, with confused vision of a single image. The same phenomena, with superadded anaesthesia of the face, indicates the implication of the fifth pair. Accompanying paralysis of the seventh is also shown by its own symptoms. In all cases, simple or compound, headache is frequently present.

This form of disease may be distinguished from strabismus by the permanency of the deviation of the globe, while in the latter it is possible occasionally for a short time to evert the eye. The impairment of vision differs also in the two cases: in strabismus the object is seen singly, from the habitual employment of one eye; in the other case vision is always confused.

The treatment must in every case be governed by the etiology.—*L'Union Médicale.*

REMARKS ON THE

VITAL STATISTICS OF THE
BOROUGH OF PLYMOUTH.

FOR THE YEAR ENDED ON THE 30TH OF
JUNE, 1850.

By Dr. W. HAMILTON.

THE close of the eventful year which has just passed away, and the appearance of the valuable tables of the vital statistics of the borough which, with

their accustomed zeal and ability, the registrars have, according to their annual custom, placed upon record for the information of posterity, call for more than a passing notice, and suggest much for grave and instructive reflection.

The first fact of importance presented to the eye on the most cursory inspection of these tables is the enormous excess of mortality they exhibit above that of any of the ten preceding years; amounting, in fact, to one-fifth of the aggregate amount. The following has been the annual mortality of the borough from the year 1839 to the present time:—

1840	1841	1842	1843	1844	1845	1846	1847	1848	1849	Sum.	Mean.	1850.	1850. Above the decennial mean.
618	843	829	1107	887	1022	749	1030	1148	1268	9,501	950.1	1,876	926.99 55 p. ct.

Of this decennial mortality, 2,201 deaths, or above 23 per cent. of the aggregate from all causes, resulted from epidemic or zymotic complaints. An examination of the tables for the past year shows, however, that, in the

brief space of twelve months only, this mortality amounted to 1,019, or nearly 46 per cent. of the aggregate decennial zymotic mortality, as will be seen by the following table of the zymotic mortality in each of the following years:—

1840	1841	1842	1843	1844	1845	1846	1847	1848	1849	Sum.	Mean.	1850.	1850. Above decennial mean.
59	130	185	400	190	219	98	157	305	458	2,201	220.1	1,019	799.363 p. cent.

What were the principal causes of this epidemic mortality will be seen in the next table;—

	18	41	1842	1843	1844	1845	1846	1847	1848	1849	Decennial.		1850.	1850 compared with the decennial mean.
											Sum.	Mean.		
Variola	1	1	46	47	63	25	9	—	18	177	387	38.7	2	36.7
Rubeola	1	43	1	17	18	41	15	46	36	19	238	23.8	20	3.8

Zymotic	57	126	182	399	185	210	91	151	301	451	2160	216	1010	794
All causes	618	843	829	1107	887	749	1030	1148	1268	9501	950.1	1876	926.99	

We have here a frightful excess of mortality, in the year which has just closed its fatal career, above the mean of the ten preceding years; amounting, from all causes, to 326, or 97 per cent. above the decennial mean, and, from the eleven causes specified in the table, to 794, or nearly 368 per cent. above the decennial mean of the mortality from those eleven causes. The greatest mortality from any single cause was in 1843, when scarlatina swept off 236, or upwards of 11 per cent. of the aggregate decennial mortality from the eleven epidemics included in the table. The next greatest was in 1849, when variola carried off 177, or above 8 per cent. of the aggregate epidemic mortality. Diarrhoea and dysentery proved fatal in the whole period to but 304, or about 14 per cent; while CHOLERA swept away, in the comparatively insignificant space of 127 days, about 1-28th part of the ten previous years, 819, or above 85 per cent. of the aggregate mortality from all causes, and nearly 38 per cent. of the aggregate decennial mortality of the causes comprised in the table. Enormous, however, as we find the preponderance on the side of this single disease, in so brief a space of time, it appears to have had little or no influence upon the mortality arising from the more usual causes.

Dr. Soltan, of this town, has, in his instructive paper on Cholera, in the MEDICAL GAZETTE for last March, fallen into the popular error that it is "an axiom connected with the history of epidemics, that, whenever they prevail, they have a tendency to stamp every other disease with their own peculiar type, especially such as are from their nature allied to them;" and he cites scarlatina and sore-throat, influenza and bronchitis, as illustrations of the opinion. But upon consulting the table last given, it will be seen that diarrhoea and dysentery—disorders which betray a manifest connection with cholera—were not sensibly affected by the presence of their Leviathan relative, but actually exceeded the mean of the ten preceding years by 246, or above 8 per cent. And so far was cholera from absorbing into itself, as it were, all the ordinary causes of mortality, that we find, on clearing the aggregate mortality of the year from that resulting from this single cause, the balance which remains exceeds the average decennial mortality by no less than 107, or up-

wards of 10 per cent.; thus corroborating, in a most unanswerable manner, the observation made by Dr. Shapter, at the 27th page of his valuable "History of Cholera in Exeter in 1832," where he says,

"It has been a not unfrequent statement, and I believe it is an opinion commonly entertained—that, during the progress of plague, all other diseases subside. The above table of deaths that occurred in Exeter shows this not to have been the case during the prevalence of the cholera. The deaths from other causes were by no means few nor far between, and were rather a large proportion to those from cholera itself. If the few deaths that occurred after the 19th of September be excluded there were from cholera 336, and from other causes 90. This latter number was scarcely less than the average mortality, which was about 50 deaths per month. So that it would appear the deaths from cholera were entirely superadded to what may perhaps be termed an otherwise not fatal season. Recent careful investigation has shown this to be the case elsewhere; and there is now reason for believing that the above opinion is founded on popular error—an error probably due to the all-absorbing topic, during the prevalence of a plague, of the plague itself, and to the habit of the public mind to assume, without any very intimate inquiry, that all the deaths which take place are from the prevailing cause—in fact, in common parlance, to die at the season of the plague is to die of the plague." This opinion is still farther confirmed by a comparison between the mortality from zymotic and that from all causes during each of the eleven years which have just expired, as in the following table, from which it may be seen that, while the deaths from epidemics in 1840 amounted only to 95 per cent. of the aggregate mortality of the year, they reached in 1850 nearly to 54 per cent. (see next page.)

We learn from this table that, while the centesimal proportion of the aggregate zymotic mortality of the entire period amounts to but 28 per cent. of the aggregate mortality from all causes, this proportion is more than doubled when the zymotic mortality of 1850 is compared with the aggregate mortality of that year from all causes. And even rejecting the surplus mortality of 819 resulting from cholera alone, a balance

Mortality from Epidemics centesimally compared with that from all Causes during the eleven last years.

	1840.	1841.	1842.	1843.	1844.	1845.	1846.	1847.	1848.	1849.	1850.	Mortality in eleven years.

of 200 deaths from other epidemics, or upwards of 10.75 per cent. of the aggregate mortality of the year, still remains. Thus clearly demonstrating the truth of Dr. Shapter's observation, that cholera was, to employ a commercial expression, a bonus thrown into the general mortality of the year.

In examining into the influence of age, Dr. Shapter appears to be somewhat in error when he says:—"Another and very general error exists, that cholera chiefly attacks the young and those of the middle ages of life, leaving exempt from its influence infancy and old age. This has arisen from an imperfect manner of viewing the subject. When the deaths resulting from cholera at each period of life are compared with the numbers living at the same period (and which is the only true mode of arriving at a sound deduction upon this point), it will be found that, during infancy, its ratio is rather above that which takes place between the ages of ten and thirty-five, when the deaths are by no means numerous; and that, after the age of thirty-five, there is a considerable increase in the relative amount of mortality; but that its greatest proportionate amount takes place about sixty-five years of age." And in support of this opinion, he gives a table of the "Deaths from Cholera in Exeter in 1832," distinguishing the ages and the duration of the attack.

But if the object of the inquiry be, as I have proposed, not simply into the fatality of cholera at different ages compared with itself, but into its fatality at those ages as measured by that of all other sources of death, Dr. Shapter's table furnishes no adequate data for instituting the comparison, and cannot enter into competition for a moment with the elaborate table given by Mr. Wyatt in the statistics before me,

deduced from official materials which Dr. Shapter unfortunately could not command.

That the mortality in the first ten years of life is, under all circumstances, greater than that of mature age, is a fact known to all who have made the statistics of life their study; and, consequently, that cholera should, in this respect, conform to the general rule, is only what might have been anticipated; and it was not my object to demonstrate by fresh evidence a statistical axiom.

In the supplementary statistics inserted in the *MEDICAL GAZETTE* of the 18th of January last I have said, at p. 105:—

"That, while the centesimal proportion of deaths from cholera falls short of the mortality from all causes by nearly 17½ per cent. under 10 years, and by about 11.17 per cent. between 60 and 100,—from 10 to 20, when youth is advancing to manhood, and beginning to be a profitable member of society, the mortality from cholera exceeds that from all causes during the eight preceding years by 3.95 per cent.; and during the meridian of life, from 20 to 60, when the individual, attaining the full maturity of his faculties, mental and corporeal, has become an important constituent of society—as the head, perhaps, of a numerous family dependent on his labours for their daily subsistence—the excess of mortality from cholera amounted to no less than 20.35 per cent. This is an important feature in the character of cholera, in Plymouth at least, which, if confirmed by experience elsewhere, will go far to correct the general belief of infancy and age furnishing the larger proportion of victims—a belief shared, as I am informed, by Dr. Shapter, who states it (unless I am misinformed) as a fact, in his history of the epidemic at Exeter.

That the popular opinion is incorrect, as far as Plymouth is concerned, the tables just given abundantly prove, furnishing matter for grave and melancholy reflection to the political economist no less than the philanthropist. Eight hundred and nineteen of those classes that earn their daily bread by the sweat of their brow and the toil of their hands have been swept from the face of the earth, of which number more than half were in the enjoyment of life, full of health, strength, and vigour, able to contribute their quota to the welfare of society; while of those who were dependent upon them for support, by far the smaller proportion was taken.

From the following re-arrangement of the table given by Dr. Shapter at page

1st period—under 10 yrs.				2d period—10 to 25 years.				3d period—25 to 64 years.				4th period—65 to 100 years.

219 of his work, so as to compare the deaths of each sex with the aggregate number of both at each of the four periods of life indicated in the passage I have extracted, it will be found that the greatest centesimal amount of mortality is, as might have been expected, on the side of the males in the first, and on that of the females in all the rest.

In a letter of the 25th of January last, Dr. Shapter asks—

“Have you not erred in stating the relative amount of deaths of the two sexes, and at the different ages, by a mere comparison with each other, instead of comparing them with the population of each sex, and the numbers living at each age of life; without taking these elements into consideration the deductions cannot be accurate: your deaths are—males, 394; females, 425. It may be that the proportion of female deaths is really less than that of males. In order to arrive at the true proposition you must compare each with the proportion of each sex comprising the population of 39,571. Your paper does not give this. Again, there is the same necessity for comparing the deaths at each age with the living at each age.”

The tables given in my last paper having been merely transcripts of those given by the registrars in their most important sheet of the statistics of cholera, I might fairly, perhaps, disclaim all responsibility for the facts they contain and the conclusions they suggest; more especially as I was not in possession of the official materials from which they were constructed. Having incorporated them, however, with my paper, and made them the basis of the opinions I advanced, I assumed to myself the responsibility of their correctness, and identified myself with those from whom they originated; I was therefore called upon to prove their correctness or admit their inaccuracy.

To do the former in the manner required by Dr. Shapter, upon the eve of a fresh enumeration of the population, and when an interval of eight years had nearly obliterated from the chart of time all the landmarks fixed in 1841, presented a barrier of difficulties I knew not how to surmount; while my conviction of the truth of my deductions forbade the adoption of the latter alternative. In this fix, as our transatlantic brethren would not unwarily term it, the genius and perseverance of Mr. Wyatt

happily came to my relief, and extricated me from my dilemma; convincing me that the arguments based upon his figures were not erroneous, although the inquiry had been conducted in a manner differing from that proposed by Dr. Shapter. This difference gave a certain degree of incompleteness to my conclusions without affecting their general truth.

"It may," as he justly observed, "be very desirable to compare the number of each age and sex that fell victims to cholera centesimally with the numbers actually living at its commencement: but such an examination, unless made conjointly with a similar inquiry into the mortality from all causes, would be equally incomplete; for it would be clearly as inconclusive and unsatisfactory to learn that cholera had swept from the stage of life any centesimal proportion of this or that sex or age living at the time, as to learn that such a proportion had been subtracted from the entire population of the town, irrespective of the results of a similar reduction from causes in permanent operation." This double inquiry has been prosecuted in the fifth of the tables

published by the registrars in their admirable synopsis of last year.

The object of that table was to exhibit in a more striking point of view the peculiarities of cholera in its effect upon the four principal stages of life, on a centesimal comparison with those of the ordinary causes of mortality, for the purpose of illustrating the curious fact that—while other epidemics, as variola, rubeola, pertussis, scarlatina, &c. limit their ravages chiefly to the young—cholera was most fatal in the two intermediate periods of existence, aiming its destructive shafts in a more especial manner at the young and vigorous, overthrowing, as was observed in my last paper, "the pillars of the social fabric," which it will take another generation to replace, and leaving comparatively intact the helplessness of infancy and the decrepitude of age.

To meet the views of Dr. Shapter, and to establish this peculiarity of cholera on an unquestionable foundation, Mr. Wyatt, at my request, compiled the following table, which he added to the annual sheet of statistics published at the close of last year:—

Mortality from Cholera during the summer of 1849, at different ages, with the centesimal proportion to the estimated numbers living, compared with the mortality from all causes during the eight preceding years.

Under the population age of	Estimated at each on the 1st of July.	MORTALITY FROM				
		All causes in 8 years.			Cholera in 127 days.	
		Total deaths.	Relative number.	Centesimal proportion.	Total deaths.	Centesimal proportion.
10 years	9,112	3,698	377	4.10	269	2.959
20	7,758	330	33	.43	66	.86
30	6,510	525	54	.82	91	1.40
40	5,966	515	52	.87	113	1.80
50	4,219	468	48	1.10	95	2.20
60	2,875	548	55	1.90	77	2.60
70	1,849	709	73	3.90	65	3.50
80	841	768	78	9.20	34	4.
90	325	418	48	12.90	6	1.80
100	116	63	6	5.20	3	2.60
Sum .	39,571	8,040	819		819	
Males .	17,516	3,965	404	2.30	394	2.24
Females	22,055	4,075	415	1.88	425	1.92

In this table the mortality from cholera at the different decennial periods of life is compared, not with the number

actually living at each period, but with a number of deaths at that age from all causes, proportionate to the total mor-

tality from cholera. This proportionate, or, as Mr. Wyatt terms it, relative number, is obtained by taking the proportion between the total number of deaths from all causes, the number at that particular age, and a number equivalent to the total mortality from cholera. Thus the total mortality from all causes was 8,040, and the total under the age of 10, 3,968. Then, as 8,040 : 3,968 :: 819 : 377, and a minute fraction which is rejected as unimportant. This number being thus obtained, the centesimal proportion to the number living is easily found as follows:—As 9,112 : 877 :: 100 : 4·10. And the centesimal mortality from cholera is similarly found—As 9,112 : 269 :: 100 : 2·959, or nearly three per cent.

From the table thus constructed we learn that, while the mortality from all causes under ten years exceeded four per cent., that from cholera under those years fell short of three per cent. But passing this mark in the calendar of

time, we find the balance progressively inclining to the opposite direction, until, at the age of 60, the mortality from cholera actually doubles that from all other causes during a period of nearly twenty-four times its actual duration, and that this preponderance of mortality from cholera continues up to the age of 80, when that from all causes resumes its normal proportion.

To place all this, however, in a still more prominent point of view, I shall here insert a table arranged upon the principle of that formerly given at page 105 of the MEDICAL GAZETTE for last March, in juxtaposition with that table, which I gladly reproduce in order to correct an error which crept in in the former, where the centesimal proportion of the mortality from cholera (13·18) is represented in the column of centesimal decrease for 45·87, the true amount, through some unaccountable inadvertence.

Age.	Centesimal proportion of deaths from						Estimated population at each period of life.	Centesimal proportion of deaths from						
	All causes in the last 8 yrs.		Cholera in 1849.		Centesimal amount of			All causes during the last 8 years.		Cholera in 1849, in the space of 127 days.		Centesimal prop.		
	No.	Centes. proport.	No.	Centes. prop.	In-crease.	De-crease.		No.	Relative prop.	Centesimal prop.	No.		Incr.	Decr.
Under 10	3698	45·995	269	32·84		28·59	9,112	9698	377	4·10	269	2·9		27·6
10 to 20	330	4·10	66	8·05	96·34		7,758	330	33	4·8	66	84	100	
20 to 60	2054	25·547	376	45·90	79·71		19,570	2054	209	1·	376	1·9	79	
60 to 100	1958	24·35	108	13·18		45·87	3,121	1958	200	6·3	108	3·4		45·7
Sum	8040		819				39,571	8400	819		819			

The first of these is the same (corrected) which has already appeared, and the second is taken from that just given, for the purpose of showing the close correspondence of the results, by whatever method they have been obtained; the comparison in both being between cholera and all other causes of mortality.

With respect to the influence of sex, Dr. Shapter expresses an opinion that "it does not appear to be very considerable." He gives a table, however, which exhibits a small centesimal excess of mortality on the part of the males, upon which he remarks that, "From the following table, in which the relative intensity and proportion of

the duration of the disease, and of death proceeding from it, are contrasted, it would appear that males are rather more obnoxious to its influence than females, a rather larger proportion of these having died (1·54 per cent. males, and 1·33 per cent. females), and at an earlier period of the attack."

At the time I transmitted my last paper to the MEDICAL GAZETTE, I was led to imagine the reverse to have been the case; but it will be seen by the last table but one that this was erroneous, the male exceeding the female mortality by 0·32 per cent, or 0·11 per cent. beyond Dr. Shapter's experience—a sufficiently close correspondence for results obtained at such a distance of time and

place. Since then I have been favoured by Mr. Wyatt with a table showing, as nearly as possible, the influence of cholera on each sex, in each of the four stages of existence which have been already employed for the purpose of comparison.

Age.	Sexes.	Estimated amount of population.	Amount of mortality resulting from cholera.	
			No.	Centesimal proportion.
Under 10 years.	Males	4,038	187	3.3
	Fem.	5,074	132	2.5
	Total	9,112	269	2.9
10 to 20	Males	3,432	22	.65
	Fem.	4,326	44	1.02
	Total	7,758	46	.86
20 to 60	Males	8,660	186	2.1
	Fem.	10,910	190	1.7
	Total	19,570	376	1.9
60 to 100	Males	1,886	49	3.5
	Fem.	1,745	59	3.3
	Total	3,181	108	3.4

We learn from this table that, while females have been the greatest sufferers, to an extent of above a quarter per cent., from cholera, between the ages of 10 and 20, at all other periods of life the preponderance was against the males, except in the more advanced periods between 60 and 100, when the fatality to both sexes approaches to within 0.2 per cent. of a perfect equality.

A similar fact has been observed in the ravages of cholera in India, whence it appears to have extended to Europe. In the narrative of a residence of four and twenty years in that country, which has proceeded within the last few months from the pen of a lady of the most masculine mind, highly cultivated understanding, and critically refined taste, published by Pelham Richardson, of Cornhill, I find it stated, at p. 283 of the first volume, that—

“Out of sixty deaths”—from cholera—“there will be forty Hindoos to twenty Mussulmans: more men are carried off than women—eight men to two women. The Mussulmans eat more nourishing food than the Hindoos, and the women are less exposed to the sun than the men.”

Thus we see that, while with us the amount of advantage enjoyed by the female portion of the community fell short of 1 per cent., it reached to 400 per cent. in India,—a difference perfectly intelligible to those who know anything of the difference of habits between the inhabitants of warm and cold climates. And this, too, will serve to account for the greater mortality in the middle periods of life, when the active employments of men expose them in a far greater degree than those at a more or less advanced period, or those of the less robust sex, to the proximate causes of the complaint. And hence it is that cholera inflicted a deeper and more permanent injury upon society than any of the more common and intelligible forms of disease, sweeping away with remorseless fury those who were its most useful members, who were in the fullest possession of their mental and physical faculties, and leaving comparatively unharmed those in whom those faculties were but in the infancy of development, or the impotence of decay.

In another respect cholera presents features which strikingly distinguish it from the general sources of mortality, and point to another form of injury inflicted by it upon society—namely, its almost total disregard of the state of gestation in females, which in almost every other disease arrests the progress of morbid action until the maternal functions have been fully completed, and the primary object of our nature accomplished. In Exeter, indeed, it appears to have made less difference than in Plymouth, and to have spared indiscriminately as many as it destroyed. On this point Dr. Shapter observes, at p. 221, that—

“With regard to the influence of the peculiarities of the female condition it may be mentioned that several cases occurred during the advanced stages of pregnancy, but that this, notwithstanding its severer symptoms were present, did not in any way affect the progress of the disease. Of two cases, between the eighth and ninth months, in both of which there were rigors, cramps, serous discharges, &c., one died, and one recovered.

“From the above it may, therefore, be generally concluded that neither age nor sex appear to exert any very great influence on the duration or virulence of the disease; irrespective of these its

course is rapid, and almost ephemeral. Unlike most epidemics, which single out for their victims persons at particular periods of life, it is, in fact, a general disease, and obeys, in the proportional amount of its mortality, the laws which govern the mortality of mankind: but then this mortality is crowded into a narrow and conspicuous place."

Conceiving that an examination of the annual and quarterly returns of births during the last eleven years would be the most certain method of obtaining light upon this important branch of the subject, I have collected these returns from the annual statistics of the registrars into the following table:—

Quarterly Births of both Sexes during the eleven years ended on the 30th of June, 1850.

Years.	Summer quarter ended 30th Sept.			Autumn quarter ended 31st Dec.			Winter quarter ended 31st March.			Spring quarter ended 30th June.			YEAR.			Years.
	M.	F.	Total	M.	F.	Total	M.	F.	Total	M.	F.	Total	M.	F.	Total	
1840	136	129	265	134	114	248	141	153	294	121	121	242	532	517	1049	1840
1841	133	118	251	128	181	269	144	143	287	135	140	275	540	532	1072	1841
1842	132	136	268	160	184	294	135	128	263	163	157	320	590	555	1145	1842
1843	132	158	290	172	154	326	163	161	324	152	135	287	619	608	1227	1843
1844	145	157	302	178	185	363	169	169	338	168	172	340	660	683	1343	1844
1845	161	176	337	201	177	378	185	155	340	177	168	340	724	671	1395	1845
1846	189	156	315	176	164	340	201	194	395	196	176	372	732	690	1422	1846
1847	174	169	343	187	170	357	182	178	360	184	177	361	727	694	1421	1847
1848	155	149	304	182	178	360	228	200	428	197	198	395	762	725	1487	1848
1849	166	183	349	207	184	391	245	204	449	237	218	455	855	789	1644	1849
1850	174	180	354	215	196	411	206	203	409	187	210	397	782	789	1571	1850
Sum.	1667	1711	3378	1940	1787	3727	1999	1888	3887	1917	1867	3784	7523	7253	14776	
Mn.	151	156	307	177	162	339	182	171	353	174	170	344	684	659	1343	

Hence we see that the number of births during the last eleven years was 14,776, giving an annual mean of 1,343, or an excess of 294 above the number born in 1840. The mean annual increase of births during the whole period may be taken at 47·5; but for the first ten years of the series it was 59·5. Had it not been for the reduction of the population in 1849-50, this rate of increase would, in all human probability, not only have been maintained, but increased. Assuming, however, only the average rate for the preceding ten years—namely, 59·5, or, in round numbers, 60, and adding this to the 1,644 born in 1848-9, we shall have 1,704 for the number of births that might have been reasonably counted upon for 1849-50; in place of which the number actually registered was only 1571, or 133 less than what it should have been, had the previous rate of increase only been maintained.

Taking the births for the year at 1704, the proportionate number for three quarters, or nine months, the ordinary term of gestation, should have been

1278; and rejecting the surplus 8 for twins, we shall have 1270 for the number of women whose gestation was more or less advanced when cholera commenced its slaughter on the 4th of July. But, as between the 1st of July, 1849, and the 31st of March, 1850, only 1,174 births were registered, the deficiency of 96 must be accounted for on the presumption that an equal number of those who should have been the mothers of those deficient children fell victims during the epidemic,—a number of deaths during pregnancy which is certainly remarkable when compared with the results of other epidemics, whose progress is generally stayed till after delivery. The age in which child-bearing most frequently occurs is from 18 to 50; and the number of females estimated to have been living between these limits at the commencement of cholera was 10,160, of whom 167 died, or 1·64 per cent.

That this reasoning, though based in a considerable degree upon hypothesis, is not in truth very wide of the mark, will be apparent from an examination

of the question in another point of view, which will present us with nearly an identical result.

On examining the table more minutely, we observe that of the 14,776 births which took place during the eleven years, 7,105 belong to the summer and autumnal quarters, and 7,671 to the remaining two; giving a mean of 646 for the two former, and of 697 for the latter; and for each quarter of the two first 318, and for each of the two last of 344. During the first of these two quarters in 1849-50, it will be remembered that cholera was raging in all its most destructive intensity; yet we find that in the first of these, comprising July, August, and September, which yielded 764, or above 60·28 per cent. of the 819 forming the aggregate harvest of the cholera mortality, the births, 354 in number, instead of being diminished by this fearful amount of mortality, and falling, as might have been expected, below the mean, actually exceeded it by 36, or upwards of 11 per cent. And in the autumn quarter, in which but 55 deaths from cholera occurred, this excess above the mean, 344, is nearly doubled, amounting to 67, or nearly 19·5 per cent. Hence it is evident that cholera had been unable, during either the meridian or the evening of its power, to make any sensible impression, or, indeed, check in the very slightest degree the onward march of population, even although, as we have just seen, nearly 2 per cent. of the female portion of the community, between the ages of 18 and 50, were its victims.

No sooner, however, had the labours of the destroyer ceased,—no sooner had society begun to recover from its state of alarm and prostration,—and no sooner had hope begun to whisper that the void created by cholera would be speedily filled up by the constantly increasing addition of births,—than we find an unexpected check given to this obliterating movement, and that, although the enemy had retired from the field, the effects of his past presence continued to be felt. Although, on comparison with the averages, an increase continues to be still perceptible in these quarters; yet, on comparison with the corresponding quarters of the preceding year, we cannot but be struck with the progressive falling off.

[To be continued.]

OF IRREGULAR CONTRACTION OF THE UTERUS.

By JAMES KIRK, M.C. GLASGOW.

If, after tying the cord and separating the child from its mother, we lay the hand over the abdomen of the latter, we will generally find the uterus lying between the umbilicus and the pubis, in the form of a solid globular body about the size of the foetal head; indicating that the uterus has contracted regularly, and that the placenta may be expected to come speedily away.

But it sometimes happens that in place of this state of matters we find one very different, namely, that the uterus instead of a globular has assumed a distinctly oblong or other abnormal shape: when this is the case, we may be certain that the uterus has contracted irregularly, and that the placenta will be retained as a consequence of this irregular contraction.

We find in actual practice that the placenta may be retained by various irregular contractions of the uterus; the following being those most commonly met with. 1st. That in which the uterus contracts firmly around the placenta, inclosing it wholly within its cavity. 2d. That in which there is a small hour-glass contraction high up. 3d. That in which there is true hour-glass action of the middle circular, or transverse fibres of the uterus, while those of the neck and fundus are uncontracted. In the first of these states, the uterus feels hard and much larger than natural when the hand is laid over the abdomen; in the second and third it has a distinctly oblong feel, sometimes presenting a ridge rising up in the middle like a sow's back. We do not recollect to have met with flooding either in the first or second variety, but always in the third.

Causes.—The causes which we have observed to predispose to irregular contraction are—1st. a very rapid delivery. 2d. severe and protracted labour; thus we see it oftenest in a first case. 3d. mental anxiety; we find it often in women whose children have been born in the absence of the medical attendant, and in young unmarried women. 4th.

we have known it to be hereditary. Dragging at the cord has also been said to give rise to it, but we have never known this to be a cause of irregular contraction.

Symptoms.—The symptoms are the oblong shape of the uterus already mentioned, and retention of the placenta with or without hemorrhage; the insertion of the cord is not felt on examination per vaginam.

Treatment.—If there is no hæmorrhage there can be no harm in waiting an hour, and making gentle friction over the uterus, particularly as patients always complain of pain on the introduction of the hand into the vagina; but if there is flooding we must immediately give 60 drops of laudanum in water, and introduce the right hand into the vagina, using the cord as guide to the placenta; then lay the left hand over the abdomen to steady the uterus; next carry the right hand up to the stricture, which is to be overcome by a gentle boring motion; then separate the adhering part of the placenta carefully with the fingers: the uterus begins to contract regularly, the placenta is removed with the hand, a bandage is applied, and the danger is over.

We are aware that it has been recommended by Gooch to keep the hand in the cavity of the uterus until it contract and expel the placenta and hand together; but we have never kept the hand longer in the uterus than till we felt it beginning to contract; and have never seen cause to alter the practice.

Perhaps the following outlines of cases which have occurred to me during the last three years may serve to set this matter in a clearer light than anything further we can say on the subject.

CASE I. Aug. 29, 1848.—Past eight in the evening, was called to attend a young unmarried woman, who had given birth to a child (her first) in the absence of all assistance at 6 P.M.: on arriving found her eyes glazed, the feather bed wet through, and cord cut close to the external parts. I immediately introduced the hand into the vagina, carried it into the uterus, and found a stricture nearly dilated, allowing it to pass easily, and the placenta adherent beyond it. Detached the placenta and brought it away. The uterus contracted, and there was no more hæmorrhage; then gave plenty of spirit, both undiluted and in toddy: she

rallied a little immediately after the placenta was removed, spoke, said she had no pain, but felt weak; swallowed freely, but presently vomited and began to sink. I immediately removed the bandage from the abdomen to examine the state of the uterus, but it had slipped down into the cavity of the pelvis: uncovered the external parts, but there was no hæmorrhage: she continued to sink, and died in about 15 minutes after my arrival. Very unfortunately I had no laudanum with me, and as the messenger had a little distance to go, she was expiring before it could be procured. This woman's mother had been, and her sisters are, when in labour, subject to hour-glass contraction.

This case may be considered as a fair example of the way in which hour-glass contraction is likely to terminate when left to itself; or when assistance is called in too late.

CASE II. July 8, 1849.—Ten in the morning, was called to attend a young unmarried woman in her first confinement; there was nothing at all unusual in the case except that the edge of the perineum gave way under my fingers as the child's head was passing over it; the placenta followed speedily, and I thought the case was over; but there was some hæmorrhage afterwards, which I at first supposed to come from the small rent in the perineum, and accordingly bathed it with spirit of turpentine (recommended as a styptic long ago by Yonge); but the hæmorrhage still continuing, and the uterus having the oblong shape when felt through the wall of the abdomen, I gave 60 drops of laudanum, and introduced the hand into the vagina, thence into the uterus, and found an hour-glass contraction about half way up: on getting through this I found a large clot of blood in the upper chamber, and brought it away with the hand. The uterus contracted regularly: a bandage was applied, and the patient made a good recovery.

This case shews that irregular contraction of the uterus may take place after the expulsion of the placenta as well as before it.

CASE III. Sept. 24, 1849.—At seven in the morning was called to attend a married woman living at a considerable distance, in her fourth confinement

Attended immediately, and waited for some time; but as her previous labour had been long and tedious, and there was no prospect of a speedy termination to the present; I left, giving directions to send for me when she became worse. After coming home I was unavoidably detained longer than I intended: no message was sent to hasten me, and before getting back the child had been born for some time. The placenta was retained, but there was neither hour-glass contraction nor hæmorrhage. The uterus felt large and globular: learnt on inquiry that the pains had suddenly become so strong and powerful that three or four had sufficed to expel the child; the uterus had then contracted around the placenta, in which state I found it on my return. After employing friction for some time with very little effect, removed the placenta with the hand, and the patient had a good recovery.

In this case there was no laudanum given, as the patient did not seem to require it. I had attended this woman in her former confinement, when she had neither irregular contraction of the uterus nor retention of the placenta.

CASE IV. March 9, 1850. — Was called to attend a married woman in labour; but as I had a considerable distance to go, and the patient had been late in sending, the child was born before my arrival; although I had gone on the first summons. The placenta had not come away. There was no hæmorrhage, but the uterus had not the proper globular shape: waited about an hour, and employed friction, but in vain. I then gave 60 drops of laudanum, introduced the hand, and removed the placenta. There was a small hour-glass contraction high up: the case ended favourably. I had attended this woman in her previous confinement, but not having so far to go was present at the birth of the child, and she had no hour-glass contraction.

CASE V. July 17, 1850. — Was called to attend a young married woman in her first confinement: she had been ill a considerable time before I saw her: labour lingering and tedious: lips of os uteri thin and sharp like the edge of a knife: for this she had an enema of starch and laudanum, as recommended by Dr. Lever, with the best effect; the character of the pains became immediately altered for the better, and the

child was born not long after; but the placenta was retained, and the uterus had not the proper globular shape; there was no hæmorrhage. After waiting nearly an hour and using friction I introduced the hand, and found a small hour-glass contraction high up, with the placenta adhering by the membranes only; removed it, and gave 60 drops of laudanum; the patient made a good recovery.

In conclusion we may state, that though we have seen many cases of irregular contraction with retained placenta, we never knew of any that did not terminate favourably except the one mentioned in this paper; and that we are inclined to think that such cases owe their immunity from after bad consequences to the large dose of laudanum given at the time of the operation; which seems to act by preventing the nerves of the uterus from resenting the injury offered to it: or, in the words of Dr. Billing, by allaying the morbid sensibility, which occurs after parturition.

Glasgow, August 28, 1850.

MORBID APPEARANCES MET WITH IN FATAL CASES OF UTERINA AT PHILADELPHIA.

The following report has been drawn up by a Committee of the College of Physicians appointed for this purpose:—

"1. In the recent subject, the peritoneal coat, like all the serous membranes, was in all remarkably dry. The lubricating serosity was deficient in the serous membranes. 2. The epithelial layer of the intestinal mucous membrane was in all the specimens either entirely removed; or was detached, adhering loosely as a pulpy layer mixed with mucus or an albuminous substance. 3. Peyer's glands were developed to a greater or less extent in all the cases examined. 4. The solitary glands were also developed, and contained in the recent subject a minute quantity of white substance. 5. The villi were denuded of their covering, but unchanged in other respects. 6. The capillaries were entire, and manifested no departure from their normal state."

In addition to the above, according to Dr. Neill, who conducted the investigations, the proper tissue of the liver was exsanguineous, but the large blood-vessels were gorged with blood. This was also the condition of all the large blood-vessels of the abdominal viscera. — *American Journal of Medical Sciences for July, 1850.*

A CASE OF
VENTRAL EXTRA-UTERINE PREG-
NANCY.

By H. M. HUGHES, M.D.
Assistant Physician to Guy's Hospital.

(From Notes by Mr. Kingsford).

WITH A DETAILED ACCOUNT OF THE POST-
MORTEM INSPECTION.

By JOHN BIRKETT,
Assistant Surgeon to Guy's Hospital.

C— F—, aged 26, was admitted into Mary Ward, Guy's Hospital, March 14th, 1849. She stated that she had been married* five years, but had never been pregnant; that the catamenia appeared at the age of 14; that they had been constantly regular at the monthly periods up to five months ago; had usually been rather scanty, and lasted about three days; and that she had generally been more or less troubled with leucorrhœa.

She was a well-formed woman, of middle stature, and of light complexion; had been always actively employed, and generally enjoyed good health, till two and a half years ago, when she was under the care of Dr. Bird for simple continued fever; since her recovery from which she had remained well up to the commencement of her present ailments.

Five months since the catamenia ceased, and about two months afterwards she observed a hard swelling in the right inguinal region. This swelling increased in size, and gradually extended over the whole hypogastrium. The mammae at the same time began to enlarge, and the areolæ to become darker than natural in colour; but she had not then, nor had she at the time of her admission, the most remote notion that she was pregnant. She continued pretty well in health, the tumor continuing constantly to increase in size, till six weeks ago, when she suddenly fainted, and upon her recovery was affected with severe pains in the lower part of the abdomen. The pains varied in intensity, but never entirely

ceased. From that time a watery discharge had constantly issued from the vagina in greater or less quantity. She also complained of bearing down, and irritability of the bladder and rectum, experiencing a frequent desire to pass her urine, and a cutting pain in the act of micturition, together with a costive state of the bowels, nausea, and loss of appetite, since the attack of syncope. She had, in consequence of her pains, which produced sleepless nights, consulted three medical practitioners; but as they all differed in opinion as to the cause of her complaint,—one stating that she was pregnant; another that she had a fever; and the third that she was suffering from inflammation of the womb,—she determined to obtain admission into a hospital.

Upon her being placed in bed, the countenance was found pallid and distressed; the tongue clean, pale, moist, and indented by the teeth; the skin natural; and the pulse small, frequent, and rather feeble. An irregularly nodulated hard tumor existed in the hypogastric region. At some parts this tumor was tender upon pressure: it extended transversely across the lower part of the abdomen, but was rather more prominent upon the right side than upon the left side. Upon examination *per vaginam*, the uterus could be felt distinctly separate from the tumor, quite moveable, somewhat enlarged, and rather flabby, and unnaturally turned aside from its normal position. A tumor about the size of a chestnut was observed in the left inguinal region: it appeared soft, moveable, and altered by pressure, and was probably situated in the integuments.

The mammae were enlarged and firm, with a dark brown areolæ, about the size of a half-crown piece, and with enlarged glandules. They presented, as was observed by one of the physician-accoucheurs, the appearance represented by the words of an old author, "*quasi inflata*."

March 15th.—After further examination, it was considered probable that, although the fetal heart could not be discovered, nor any "uterine souffle" (so called) distinctly heard, the patient was pregnant, and that the fœtus was extra uterine. The bladder was considerably distended; the bowels were confined; and the vaginal discharge was considerable. It was ordered that

* It afterwards appeared doubtful if she had been married at all; it was stated that she had been a prostitute, but had lived with one man for the five years above mentioned.

the catheter should be introduced; that a fetid enema should be administered; and that she should take three times a day a draught containing rhubarb, cinchona, and oilbanum.

21st.—She complained of general abdominal pain, and some local tenderness; and the physician-accoucheur was requested to examine her. In the interim she was ordered to have half a grain of opium, to be taken when the pain was severe, eight leeches applied to the tender part of the right inguinal region, and afterwards to have a poultice to the abdomen. The obstetric physicians, while they acknowledged the probability, from the general and local symptoms, of the existence of extra-uterine pregnancy, supposed that, from the absence of any indication of foetal pulsation, from the presence of milk in the breasts (for it could now be pressed from both nipples), and from the consideration that if the foetus were dead the milk would have ceased to have been secreted, the symptoms, both local and general, might possibly arise from disease of the ovary, independently of pregnancy.

22nd.—The leeches afforded her much relief: she had passed a good night, and was much refreshed, and altogether much more comfortable in the morning.

26th.—The pains were much more severe, and entirely deprived her of rest: the bowels had not acted for two days. Ordered Enema Terebinthinæ stat. Pergat.

27th.—The countenance was flushed and rather anxious, and she complained greatly of pain at the hypogastrium: the tongue, however, was moist and clean; the skin natural; and the pulse not excited. The catheter was again introduced, in consequence of her having passed only a little urine with difficulty; but only half a pint of clear straw-coloured fluid was removed. The vaginal discharge was profuse: and she complained of vomiting, and loss of appetite. Ordered Soda Water; Cataplasma Lini.; hypogastrio applicand.; Pulv. Rhei. gr. x.; Pulv. Potass. Sulphat. 3ss., statim sumend; Opii gr. ss. 4ta quaque hora.

29th.—She was altogether better yesterday; but had passed a sleepless night: the pains were still very acute in the hypogastrium; the countenance was anxious, and the face alternately flushed and pale; the bowels were moderately

acted on by the powder, and continued very slightly relaxed. Ordered to continue the Opium during the day, and to take half a grain of Hydrochlorate of Morphia at bed-time.

30th.—She had a good night, but complained much of pain, and particularly of a dragging at the waist. She expressed much annoyance from a constant thirst; and the Opium was consequently omitted, but the Morphia continued.

31st.—She complained more of pain; and the local tenderness being considerable, five leeches were ordered to be applied; as on a former occasion they had afforded her so much relief. At ten p.m. she said she felt easier since the application of the leeches, and appeared inclined to sleep.

April 1st.—It was stated by the patient in the adjoining bed that our patient awoke about 4 A.M., and complained of great pain, and expressed a wish for the morning, that she might see the sister of the ward and the doctors. She continued very restless for the space of two hours, and then suddenly called for something to drink; after taking some water she composed herself apparently to sleep; but at the expiration of half an hour the nurse again visited her, and found her dead.

Necropsy, 33 hours after death.

The surface of the body was remarkably exsanguine. The joints, although rigid, were with facility flexed. At the junction of the mesogastric region with the hypogastric, and of the left iliac fossa with the pubic region, a firm and rather hard tumor elevated the abdominal parietes. The mammae were well developed, and a plentiful secretion of thick, creamy, opaque white, lacteal fluid could be expressed from the nipples. The body appeared to have been well nourished.

The abdominal cavity contained a large quantity of bloody serum and large masses of recently coagulated lymph. The great omentum extended downwards into the pelvis, and was adherent to the peritoneal covering of the hypogastric abdominal walls. The stomach and transverse colon were pulled down by this adhesion. The alimentary canal was normal, except that a few adhesions extended between the cæcum and sigmoid flexure of the

colon and abdominal tumor. The appendix cæci was firmly adherent to the posterior wall of the tumor.

Turning downwards the hypogastric abdominal walls and omentum, a large mass was seen filling up the pelvis. Its longest diameter was placed transversely over the brim of this cavity. The general outline of this tumor was triangular, the apex descending into the pelvic region. The base of this triangular mass was smooth, and seemed to be covered by the peritoneum. The largest part, however, appeared to consist of coagulated blood entangled in abnormal adhesions. Evidences of old peritoneal inflammation existed in different parts of the peritoneal membrane.

The urinary organs were normal. The direction of the axis of the uterus was towards the left side. It was of a larger size than is usually seen in the unimpregnated condition. It was remarkably exsanguine. Projecting from the os was a very firm plastic plug, of a soft solid consistence, something between mucus and gelatine, of a pale yellow tint, and very cohesive. The cavity of the uterus was lined with a soft flocculent tissue, of a pale yellow tint and speckled appearance. The right uterine appendages were bound together by slight adhesions. The right ovary was corrugated, and contained small Graafian vesicles. The right fallopian tube had a small cyst developed in it at about $1\frac{1}{2}$ inches from its uterine aperture. From the uterus to the site of this cyst it was pervious and normal; but between the cyst and the fimbriated extremity the tube was dilated and filled with mucous flocculent matter. Where the tube and cyst were in contact the former appeared to be obstructed. The left uterine appendages formed integral portions of the tumor. The left ovary was corrugated, and it contained a small cyst, which had the appearances of a recently formed corpus luteum. The left fallopian tube was pervious and normal along the whole canal; but its fimbriated extremity was adherent to the tumor.

To the left uterine appendages a cyst was attached, which appeared to be composed of an expansion of the broad uterine ligaments, a new membrane, and a portion of the great omentum. The anterior surface of the cyst was formed by the omentum: a corrugated and ex-

panded portion. The posterior surface was formed by the left broad ligament. Between this cyst and the uterus were masses of coagula, apparently the result of old and recent effusions of blood. The cyst contained a male fœtus of about the fifth month of development, and perfectly formed, with the exception of two small excrecences on the head. The umbilical cord and placenta were perfect. The amnion was well formed; but there was no appreciable quantity of liquor amnii. The back of the fœtus was directed towards the mother's umbilicus; its head to her left ileum.

When that portion of omentum composing the cyst was examined, some enormously distended veins were found attached to a red mass, which proved to be the placenta. In fact, this, which corresponded with the uterine surface of the placenta, was attached to a part of the omentum—the analogue of the internal surface of the uterus. In one point a separation had taken place; and, from the appearance of the coagula in its vicinity, it was clear that here the fatal hæmorrhage had occurred. The vessels which carried blood to the placenta were from the uterine arteries. The numerous enlarged veins in the great omentum returned the blood into the mother's circulation. The ovum, escaping from the left ovary must have fallen upon the superior surface of the left broad ligaments, and there taken root.

It is highly probable that, as the anterior surface of the omentum was adherent to the peritoneal aspect of the anterior abdominal walls, and by its posterior aspect to the placenta, some action of the abdominal muscles, during her fits of restlessness, may have given rise to the separation of the omentum from the placenta, and hence the fatal hæmorrhage.

I cannot state that there were evidences of old adhesions existing about the uterine appendages before the abnormal conception. All I saw appeared to be produced by the tumor itself.

THE PUBLIC HEALTH ACT IN WORCESTER.
THE citizens of Worcester have declined, on the plea of expense, to appoint a medical officer under the Public Health Act.

MEDICAL GAZETTE.

FRIDAY, SEPTEMBER 27, 1850.

BEFORE another number of this journal issues from the press a new medical session will have commenced. During the recess but few changes appear to have taken place in the Metropolitan and Provincial Schools. We recognise in the advertised lists the same well-known names as teachers. The only important change in the metropolis is, that the Professorship of Surgery at University College, vacated by Mr. Arnott, is now filled by Mr. Erichsen, a gentleman who has already earned a good reputation as a practical surgeon. The order of the courses to be pursued by the student remains unchanged; for we cannot conceal the fact that we are still jogging on in an unreformed state. Again, the amount of the fees for Hall and College is calculated with very great precision, so that a student may know to a fraction what will be the cost of his medical education; and he will also find, in the advertisements of different schools, every variety of accommodation as to the time and mode of payment.

It is not our custom to recommend to the student the selection of one medical school in preference to another. There are, however, some points on which it may be proper to make a few observations. We will suppose that the student is desirous of obtaining a sound knowledge of his *profession*, and not merely of acquiring such a superficial acquaintance with the various branches of medical science as will enable him (by the aid of a grinder) to procure the *diplomas* of the College and Hall. Under these circumstances he should select a school to which there is

attached a hospital or infirmary, in the wards of which clinical instruction is regularly imparted by the attendant physicians and surgeons. A *medical* school unconnected with an hospital is a misnomer; and it is our belief that whatever temptation is held out to the student in the shape of "ruinously low" fees, or an abundance of prizes, &c., his time will be lost by associating himself with such an establishment. This is so well known, that the suggestion is scarcely needed, except for the guidance of those who have no professional relation or friend to advise them on the selection of a place of study. Of the Hospital Schools of London, and the reputation of the medical officers associated with them, we need say nothing. These institutions are now under such control and management, that there is not one in which, with ordinary care and industry, a student may not acquire an excellent knowledge of his profession. It is, however, a fact calling for notice, that there is a sort of advertising competition among these establishments, against which we must put neivices on their guard. Among the Metropolitan schools which have acquired good repute as seats of study, the difference in the total amount of fees required for the College and Hall qualifications is so small, as to be scarcely a matter for consideration. Competition has here taken another form. Scholarships and prizes on a profuse scale are held out as tempting baits to allure the wavering student. The whole affair appears like a medical lottery, in which every student who purchases a ticket is almost sure of obtaining a prize of some description. Such schemes may be expedient and even necessary in some cases to attract young gentlemen fresh from the country; but we doubt the propriety of allowing the character of a school, as a place of medical *education*, to depend upon such a system. The

only valuable prizes to a medical student are the dresserships, clinical clerkships, and other professional offices about a hospital; because in working for them, he cannot fail to improve himself in a practical knowledge of his profession. If tempted by a gold medal, or a handsome prize in money, to work on some special subject, there can be no doubt that his general medical education must be neglected. During his studentship he may make a good medalist, and an honoured prizeman, but in after life he will be found an indifferent practitioner. It is, we believe, within the experience of most students and teachers, that men whose attention is thus directed to one subject are marked throughout the session as neglectful of other branches of their education.

We observe in the advertisement of one Hospital School, that a prize of one hundred pounds, to be awarded in 1851, is offered for the best essay "*On the Chemical and Physiological Action of Mercurial Preparations.*" We are inclined to ask seriously what can be the motive for making such an offer as this? If such a prize had been thrown open to the profession generally we could understand the object of it; but when we find that it is presented as an October attraction to gentlemen who have yet to learn chemistry and physiology, and who can have had no practical experience, without which such an essay would be worthless, the offer is simply ridiculous. It may, however, have a mischievous effect: it may induce some ten or twenty students to devote their time to the preparation of essays on a subject on which a professional standing of ten years, with good opportunities of acquiring experience, and a constant attention to the rapid progress of chemical and physiological sciences, would alone qualify a man to write. Under these circumstances the competing students must be withdrawn

from their proper duties; and we doubt not, that all but the successful candidate will regret the waste of valuable time. We have seldom met with a more absurd illustration of the injudicious extent to which the students' prize-essay system can be carried than this.

The lists of advertisements further show us that the commercial value of the lectures and practice required in the metropolis for the College and Hall qualifications, varies from *fifty-seven to one hundred guineas*—a fact which shows either that the professors at some schools are content to impart their experience at a very small profit, or that those belonging to other schools are greatly overpaid for their services. The quality of the instruction, and the relative means of teaching, are, we fear, not sufficiently investigated by the licensing boards. The student must therefore look to these points himself, or he will find when too late, that it will be necessary to withdraw from one school and enter to another. As a summary of our advice, we shall remark:—Select a school to which an hospital is attached; and look with distrust upon those establishments whose principal recommendations are very low fees, or an abundance of medals and prizes.

We have now before us the last Annual Report of the Sydenham Society, and we are glad to perceive, from the contents of this document, that the members have already derived many advantages from its establishment. Our readers are doubtless aware that this Society has been founded for the publication, in a cheap form, of—I. Reprints of standard English works: and in this department it has issued, during the last seven years, the entire works of Sydenham, Harvey, and Hewson. II. Miscellaneous selections from the ancient and from the earlier modern

authors. Three works which fall under this division have been published. III. Digests of the works of old and voluminous authors, British and foreign. For satisfactory reasons assigned in the Report, this part of the original plan has not yet been carried out. IV. Translations of the Greek and Latin medical authors, and of works in the Arabic, and other eastern tongues. Under this department several works have been issued, including the seven books of Paulus Ægineta, the genuine works of Hippocrates, and the Treatise of Rhazes on the Small-pox. V. Translations of foreign works, of which several valuable volumes have appeared. VI. Original works of merit. The Council admit that no work referable to this division has yet been published. The subject has been well considered, but some serious difficulties have presented themselves in carrying out the scheme. It is stated that a medical bibliography of all countries is now in preparation. This cannot fail to prove a most valuable aid to the student of medical literature.

"In addition to the Bibliography, the following works are also in preparation, some of which are ready for the press:

"I. The remaining portions of Rokitsansky's Pathological Anatomy, now the only one of the Society's publications which is not completed.

"II. A volume on Epidemic Catarrh.

"III. The writings of Unzer and Prochaska on the Nervous System.

"IV. A further Selection from the Works of Dupuytren.

"V. A volume to comprise the most important Writings of the earlier British Physiologists; and,

"Lastly, during the past year, the Council have made arrangements for an edition of Hunter's Plates of the Gravid Uterus."

That the Society has not been idle during the seven years of its existence is apparent from the following extract from the Report:—

"Those who have been members of

the Society from the beginning have now received, for their seven annual subscriptions of £1. 1s., twenty-three 8vo volumes, which have been got up in excellent style; the paper, printing, and binding, being the best that could be obtained without entailing any extravagant expenditure. Each volume has on an average 475 pages; the whole twenty-three volumes comprising 11,000 very full pages of letter-press, and twenty-six illustrative plates. This, it will be found, is as much, if not more matter than other similar societies, with a far greater number of members, have been able to issue. The ordinary publishing price of the Sydenham Society's works would probably be about £16 or £17. It is, therefore, scarcely necessary to adduce further proof of the mercantile success of the Society. It may, however, be mentioned, that the Sydenham Society's books are eagerly sought after in the second-hand book market, where a few copies have found their way, chiefly through the death of members, and have always fetched good prices.*"

We find from the Report that the publications of the Society have been already distributed among 2543 members of the profession—a fact which shows the great extent to which medical literature has been already diffused by this Society. From its *quasi*-commercial character it is clear that the greater the number of subscribers the larger will be its sphere of usefulness, and the greater the amount of benefit conferred upon each subscriber. The Society is deserving of the patronage of all those who take an interest in the diffusion of medical literature.

* We subjoin a list of the works already issued by the Society:—*For the First Year, 1843-4*—Hecker's Epidemics of the Middle Ages, one vol. 8vo. pp. xx. 380; Louis on Phthisis, one vol. 8vo. pp. xxxv. 871; Th. Sydenham, Opera Omnia, one vol. 8vo. pp. xxx. 668. *For the Second Year, 1844-5*—The Seven Books of Paulus Ægineta, vol. i. pp. xxviii. 668; Observations on Aneurism, one vol. 8vo. pp. xii. 524; Simon's Animal Chemistry, vol. i. 8vo. pp. xx. 360, plate. *For the Third Year, 1845-6*—Simon's Animal Chemistry, vol. ii. 8vo. pp. xii. 360, 2 plates; Paulus Ægineta, vol. ii. 8vo. pp. xi. 611; Haase's Pathology, 8vo. pp. xvi. 400. *For the Fourth Year, 1846-7*—The Works of W. Hewson, in one vol. 8vo. pp. lvi. 360, portrait and 8 plates; Dupuytren's Lectures on Diseases and Injuries of Bones, one vol. 8vo. pp. xvi. 459; The Works of W. Har-

Reviews.

Medical Biographies: Oxford Series.

The Lives of Charles Brandon Trye, Surgeon; George Cheyne, M.D.; Thos. Harrison Burder, M.D.; Sir James Stonhouse, Bart., M.D. Oxford: Parker. London: Churchill.

THIS series of works was originally published anonymously, but the fact is now well known that they have been produced under the editorship of the learned Dr. Greenhill, of Oxford, known to the profession as the editor of several valuable works in medical literature, and among these of the Latin edition of Sydenham's works, and of the translation from the Arabic of Rhazes on the Small Pox, both published by the Sydenham Society.

Our object in now bringing these biographies under notice is not so much to laud eminent medical attainments,—for perhaps of the four medical men above referred to, the name of one only is known far beyond his own immediate circle,—but rather to impress upon our readers the great and all-important lesson which it is the desire of the editor to inculcate by their publication—viz. that medical skill and great professional and other acquirements are perfectly compatible with, and will receive lustre from, their union with high spiritual attainments; that the perfect medical character is best seen in the earnest and sincere Christian; and that a due sense of the

value of the soul can alone give a due sense of the physician's responsibility to his patient.

Although our limits will not permit us to borrow many particulars of the subjects of the several memoirs, we must not dismiss them without a brief notice of each.

Mr. Trye was many years an eminent surgical practitioner in Gloucester, but still better known and endeared to his fellow-townsmen by his attention and benevolence to the poor, by his strict integrity and genuine piety founded on a firm and influential belief in the truths of Christianity. Mr. Trye died in 1811.

Dr. Cheyne's name is more widely known in medical literature, which he enriched by many productions between the years 1702 and 1742, in which year he died. His pen did also some service in the cause of religion. "In a sketch of his character that appeared in one of the papers at the time of his death, he is called 'a learned physician, a sound Christian, a deep scholar, and a warm friend;' and it was said 'that those who best knew him, most loved him.'"

"Dr. Cheyne followed the business of his profession with great diligence and attention, dividing his time between London and Bath"—a mode of practice, we may observe, not so likely to prosper in the present day, even under the advantages of railroad travelling.

Dr. Burder's reputation, though partly founded on his professional attainments, is mainly based on his religious character. He practised several years in London; but the feebleness of his health, which forbade his so prosecuting the practice of medicine as to rise to eminence therein, at last compelled him to relinquish its pursuit entirely. Dr. Burder died in 1843. His writings were not numerous, but excellent in their way; he is more especially and usefully known as the author of "Letters from a Senior to a Junior Physician," which have also been republished by Dr. Greenhill.

Of Sir James Stonhouse it is recorded that he was a successful practitioner at Northampton, and the intimate friend of Doddridge and Hervey; and that he relinquished practice and took Holy Orders.

However different the intellectual endowments and professional attainments of these several individuals may have been, they all possessed the

vey, M.D., complete in one vol. 8vo. pp. xcvi. 624. For the 5th year, 1847-8—Paulus Ægineta, vol. iii., pp. viii. 653.; Feuchtersleben's Medical Psychology, pp. xx. 393.; Microscopical Researches of Schwann and Schleiden, pp. xx. 268, 6 plates; Memoirs of the French Academy of Surgery, pp. x. 293. For the sixth year, 1848-9—Rhazes on the Small-pox and Measles, 8vo. pp. viii. 212; The Genuine Works of Hippocrates, translated from the Greek, vol. i., 8vo. pp. x. 466; The Works of Sydenham, translated from the Latin, vol. i., 8vo. pp. cvi. 376; Rokitsansky's Pathological Anatomy, vol. ii. (the first issued), 8vo. pp. 875. For the seventh year, 1849-50—The Genuine Works of Hippocrates, vol. ii., pp. 406; Essays on the Puerperal Fever, and other Diseases peculiar to Women, 8vo. pp. 552; The Works of Sydenham, translated from the Latin, vol. ii., pp. 396.

Notice.—New Members may still obtain the first, fourth, fifth, and sixth year's works; but of the second and third year's books none remain. In lieu of the third volume of Paulus Ægineta, new members will receive a copy of some other work; so that, on commencing with the fourth, or either of the subsequent years, the series of books which they will obtain will be complete in themselves.

"one thing needful." Although their biographies afford us but little of strictly medical interest to transfer to our pages, yet the records of their lives, and of the gradual development of their Christian character, as contained in these volumes, will furnish the best of lessons to those who may peruse them. Their histories are truly "philosophy teaching by example"—and examples indeed, teaching true philosophy.

There is one feature in the biographies which deserves especial notice—namely, the copious annotations by the editor: these supply much valuable information, respecting many persons and events, which could only have been obtained by laborious research and extensive erudition.

We may notice also that no small share of interest which each of the volumes before us possesses, is derived from the correspondence with individuals eminent for religious and medical attainments, which is contained therein.

We might draw many contrasts in favour of the unobtrusive goodness of such men as Trye, Cheyne, Burder, and Stonhouse, when compared with more extended reputations, solely professional;—we might, for example, set against these instances many of greater celebrity,—but we content ourselves with one parallel, and submit to our readers to select between goodness and mere greatness.

Our continental brethren have recently, with their wonted pomp and ceremony, inaugurated a statue to the memory of Larrey, in the Military Hospital of Val-de-Grâce, Paris. To grace the ceremony, a number of cripples who had been operated upon by Larrey on the field of battle were ranged at the base of the statue; with these stood the remains of "*la grande armée*," dressed in their historical costumes; and among them, the nephew of "the Emperor," who, as President of the French Republic, attended in its name to do honour to departed surgical skill. All the learned, civil, and political institutions of Paris sent their representatives, to add dignity to the ceremony. Eloquent laudatory orations were delivered in praise of Larrey and of French surgery. The skill, the courage, and the perseverance, and all the moral qualities of the deceased, were lauded to the skies,—but of the highest of all praise, that he was an eminent

Christian, we are not informed by his eulogists: perhaps this was not regarded as being a qualification necessary for the erection of a statue at Val-de-Grâce.

Some of our brethren on this side the Channel seem disposed to regard such posthumous honours as greatly enviable. If we may judge from the frequency with which we meet with the discussion of the topic in periodicals, the public award of honours to members of the medical profession is one which seems desirable to many, and the attainment of which occupies much of their attention. It should not be forgotten, however, that our mission is to the homes of our neighbours; our instruments are kindness, skill, and attention, and we doubt if these be compatible with the introduction of the elements of ambition as an inducement to the performance of our duties.

We are disposed to regard it as a higher honour to the profession, to be ranked among the "good," than among the merely "great:" we doubt not that the majority of our readers will concur in this opinion.

Some more of these biographies are promised, which we shall gladly welcome. Each sketch "forms part of a series of Christian medical biographies which it is proposed to publish, of those physicians who have been most eminent for their piety, in whatever age and country they may have lived;" and it is to spread the influence of their good example that we would urge upon our readers to possess themselves of these volumes.

Medical Portraits. Drawn by J. H. MACGILL, and printed by HANHART. 1850.

We have now before us, of the series of medical portraits of which we have already been able to speak in high terms of approbation, lithographic likenesses of *Mr. F. C. Skay and Professor Paget*, of St. Bartholomew's Hospital; of *Mr. Hancock* and *Mr. Avery*, surgeons of the Charing Cross Hospital; of *Mr. James Ronald Martin*, Presidency Surgeon, and Surgeon to the Body Guard of the Governor-General of India—author, in conjunction with the late Dr. Johnson, of a Treatise on the Diseases of Tropical Climates; and lastly, of the late *Sir William Ellis*, of

Hanwell. Of these six portraits, five are marked by the hand of a master. We have never seen the lithographic crayon applied to portraiture with such success as by Mr. J. H. Maguire. His drawings are clear, the position varied, and, while the greatest pains have been bestowed on the features, the details of the dress are accurately and carefully given. The portrait of Professor Paget is an admirable likeness, and is a beautiful specimen of lithographic art. The portrait of the late Sir William Ellis is evidently by a different hand, and in a different style. We recommend this serial collection to all who wish to have a real gallery of medical portraits.

Proceedings of Societies.

ACADEMY OF SCIENCES, PARIS.

September 30, 1850.

On the General Diffusion of Iodine—Gôitre—Researches on the Constitution of certain Waters.

M. CHATIN, who has been for some time past engaged with investigations on the existence of iodine in crevasses and other *fresh water* vegetables, has presented another long communication to the Academy, having for its object to show the general diffusion of iodine throughout various departments of nature, and especially in fresh water and the plants which vegetate therein. M. Chatin has ascertained the presence of iodine in aquatic plants, not only of European growth, but in those of Asia, Africa, America, and New Holland, shewing the general diffusion of this body on the surface of the earth. He also finds that the ashes of vegetables which grow out of contact with water do not contain iodine. Hence M. Chatin derives the inference, that the state of the globe at different epoch may be deduced from an analysis of the ashes of the vegetables then produced. Thus, for instance, coal rich in iodine would be the produce of vegetables which flourish whilst the waters covered the surface of the earth: anthracite, containing a less proportion of iodine than coal, would show that its formation was derived from an admixture of terrestrial plants with the great cryptogamous plants of the coal formation, and therefore at a period subsequent to the appearing of the dry land; whilst the lignites, which contain little or no iodine, indicate their formation to have occurred

during the present condition of our globe. Iodine reappears in the ashes of peat, the modern detritus of the stunted vegetation of our marshes and bogs. Graphite, from the large proportion of iodine which it contains, would appear to claim a place amongst the productions of an organic and aqueous origin, representing the vegetation of a period long anterior to the coal formation, and probably the first which appeared on the surface of the earth after it had become cooled.

The animals which live in fresh water were found by M. Chatin to contain iodine, and in larger proportion than the plants grown under the same circumstances. M. Chatin is of opinion that the richness of waters in iodine may be correctly deduced from the amount of iron they contain: so that the waters to which we apply the term ferruginous may also be called ioduretted waters. The waters of volcanic formations appear from M. Chatin's researches to contain more iodine than the sedimentary strata. The waters containing much lime and magnesia salts usually show but slight traces of iodine. The usual form of the appearance of iron in these waters is that of iodide of iron.

Iodine exists also in some terrestrial plants and animals, especially in plants frequently watered. The salts of soda, potash, and magnesia, as ordinarily met with in commerce, almost always contain appreciable quantities of iodine. Fermented liquors are found by M. Chatin to contain iodine, but in less proportion than the mean of fresh waters. Wines also contain iodine, varying in quantity according to the variable nature of the soil producing them. Milk is richer in iodine than wine, and asses' milk contains more than the milk of the cow. The quantity of iodine appears to be in an inverse proportion to the abundance of that secretion. Eggs are extremely rich in iodine. A hen's egg of the weight of 2½ ounces contains more iodine than a quart of milk, or than two quarts of wine or good water.

Iodine exists also, according to M. Chatin, in arable soil, in sulphur, the ores of iron in peroxide of manganese, and in sulphuret of mercury. M. Chatin considers it very probable that the want of iodine, or its existence in too small a proportion in the waters employed in different countries for domestic purposes, is the principal cause of gôitre, and recommends the employment in cases of this affection of such diet as is found to contain a somewhat large proportion of iodine.

As somewhat in connection with the above, we may mention some recent researches of M. Maumené on the water of Rheims. M. Maumené states that he is

unable to find the least trace of magnesia either in the waters or in the soil; and to this want of magnesia in the water he attributes the almost universal prevalence of the goitre in that city, there being but few families in which one or more persons are to be found exempt from this affection.

In his investigations on these waters, M. Maumené notices a fact somewhat opposed to preconceived opinions; it is, that water containing sulphate of lime is not always decomposed by soap. His experiments go to prove that all the salts of lime, without exception, may exist in somewhat considerable proportion in water which does not contain other salts, without producing a deposit on the addition of soap: the maximum limit he finds to be about 10 grains of sulphate of lime, 64 grains of chloride of calcium, and 10 grains of nitrate of lime, each, in one quart of water. Carbonate of lime would at first sight appear to prove an exception; but the addition of soap produces only an opacity up to a certain limit, beyond which a deposit takes place. M. Maumené considers that the insoluble carbonates do not exist in water in the state of bicarbonates, as has generally been supposed. If the carbonic acid influences the solubility of these carbonates, it is not, he considers, by reason of any chemical action, but simply in virtue of a dissolving force. Carbonic acid is not the sole agent in the solution of the carbonates; there are certain salts which have the power of destroying this insolubility. Hence he concludes that in natural waters the carbonates are dissolved partly by the action of carbonic acid, and partly by the action of other saline substances.

POISONING WITH DULCAMARA. BY DR. PLATSCHKE.

A MAN, 40 years of age, who was using decoction of dulcamara-stalks for a cough, took, one forenoon, from three to four quarts prepared from a peck of the stalks. In the evening he was suddenly seized with numbness in his limbs, and pains in the knees and elbows, dryness of the throat, and paralysis of the tongue. These symptoms increased so much in the course of three or four hours, that he could scarcely move either his limbs or tongue. The head remained unaffected, consciousness unimpaired, the pulse quiet, but small and rather hard, breathing regular, the skin cool; there was neither nausea nor vomiting. From the time which had elapsed since taking the decoction, the administration of emetics was contra-indicated; recourse was therefore had to stimulants. Camphor was given freely, and the symptoms gradually disappeared. — *Casper's Wochenachrift*.

Hospital and Infirmary Reports.

ST. BARTHOLOMEW'S HOSPITAL.

Necrosis of a Portion of the Os Calcis—Extraction of the Dead Bone.

JAMES RAGGON, *et. 16*, an apparently healthy lad, fell down stairs a year ago and hurt his left heel. The injury was followed by swelling and severe pain, and subsequently by a discharge of matter, in which a few small pieces of dead bone were discovered.

July 26th, 1850, admitted under Mr. Stanley. The neighbourhood of the heel and malleolus is swelled, and there is very little motion in the ankle-joint. There are four fistulous openings in the skin, on the outer side of the os calcis; and through one of these, behind and below the outer malleolus, dead bone can be plainly felt with the probe, in a situation that may readily be approached. An operation for its removal was therefore proposed, and performed in the following way, on Saturday, Aug. 17th.

When the patient had inhaled sufficient chloroform to be insensible to pain, Mr. Stanley made a semilunar incision along the outer margin of the calcis and insertion of the tendo-achillis, and reflected the integuments, which formed a thick flap, from the outer surface of the calcis, and exposed a loose piece of dead bone, about the size of a nutmeg, occupying a cup-shaped cavity, with a highly vascular lining, in the outer wall of the calcis. The cavity which lodged it was so superficial, that the dead bone was removed without further cutting; and when the integuments were replaced, very little injury appeared to have been inflicted on the neighbouring parts by the operation.

Sept. 5th.—The wound is healed, and all the sinuses also, except one, which is healing. The swelling is diminished, and the foot promises to be nearly as serviceable as the other.

Necrosis and Removal of the first and second Metatarsal Bones.

Sarah Jackson, *et. 36*, a pale and thin woman from the country, in the habit of working hard, states that seven months ago her right foot became painful, swelled on its inner side, pattered, and was lanced by a surgeon. The wound did not heal, and the pain continued; and, to avoid pressure on the part, she contracted the habit of walking on the outer margin of the foot.

July 25th, 1850, admitted under Mr.

Stanley. The sole of the foot could not be placed flat on the ground, the inner side being raised and fixed in the position of an ordinary talipes varus. There was a wound on the inner side of the foot, over the first metatarsal bone, through which dead bone was felt. In the beginning of August Mr. Stanley enlarged the wound, and extracted nearly the half of the first metatarsal bone, which was dead, and detached from the surrounding tissues; and, on introducing his finger, discovered that the remainder of this, as well as the whole of the second metatarsal bone, was dead, and that each bone was broken in two about its centre; and, as is usual in necrosis of the metatarsus, there was no attempt on the part of nature to form new bone. As separation of the dead bone without surgical interference would, in this case, be a very long and tedious process, which the weak state of the patient could ill afford, Mr. Stanley advised its removal, as well as that of the phalanges, which could be of no use if allowed to remain without their metatarsal bones.

Aug. 10th.—The operation was performed while the patient was under the influence of chloroform. The necrosis had not extended beyond the two inner metatarsal bones; these were removed, together with their phalanges, and the integuments were brought together by sutures.

Sept. 6th.—The patient's health has improved since the operation, the wound is nearly healed, and the cloistrix is on the upper part of the foot, where it will be free from pressure. The varus of course remains, and probably will not be detrimental to a foot which possesses its three outer toes only.

Necrosis and Reproduction of the Clavicle.

Caroline Gurney, *et. 16*, states that about three months ago she was much fatigued by carrying a child on the left arm; that she subsequently discovered a swelling, and experienced a great deal of pain, in the neighbourhood of the left clavicle, and was quite unable to move the arm on that side.

Sept. 28th, 1847, admitted under Mr. Lloyd. There is swelling and fluctuation over the centre of the clavicle. On pressing the bone a crepitus may be felt. The arm is powerless. Some leeches and a cold lotion were applied, and the arm was banded to her side.

During her stay in the hospital she was attacked with erysipelas of such a severe nature, that at one time her life was despaired of. The swelling over the clavicle was opened, and pus was discharged from the wound.

Dec. 6th.—The erysipelas has left her in a very weak and emaciated condition, from

which she is slowly recovering. Pus is still discharged from an opening over the clavicle, and the bone is not yet united.

Feb. 6th, 1848.—She is now regaining strength rapidly, and has recovered partial use of the arm. The clavicle is united, but tender on pressure, and surrounded by hardness and thickening of the adjacent parts.—Discharged.

In May, 1850, she came to the hospital to show a piece of bone that she had herself extracted from her shoulder. She stated that the end of it projected through the skin, and, being loose, she took hold of it, and drew out what proved to be the clavicle, nearly entire, wanting only its two articular extremities. It is smooth and white on its surface, and has a large canal through its centre, caused by the absorption of its cancellous structure. A new clavicle had been formed, and appeared to answer every purpose remarkably well; its surface was rather irregular, and adherent to the skin at different places. She had very good use in the arm, and was able to work as a domestic servant.

The spot where the bone originally gave way must have been near one of its extremities, as there was no fracture in the necrosed portion now produced. And at the time she left the hospital the dead clavicle must have been inclosed in a sheath of new bone strong enough to allow partial use of the arm, and to give the clavicle the appearance of having united as well as was expected after such a severe attack of erysipelas.

Excision of an Epithelial Cancer from the lowest Part of the Back.

Jane Collins, *et. 59*, states that a year ago she experienced a painful sensation at the lower part of her back, and discovered a small tumor in this situation. It has increased in size, and has frequently been very painful, especially on slight irritation or pressure from her dress, during the last six months.

Aug. 28th, 1850, admitted under Mr. Paget. A circumscribed subcutaneous tumor, about the size of a walnut, of a dull grey or nearly black appearance, prominent and elastic in the centre, but firm and extended in the base, moving readily in the subjacent fat, but adherent to the skin covering it, which is thin, was situated nearly in the middle line of the back, over the sacrum. As it had somewhat the appearance of melanosis, the patient was asked whether she had previously noticed any mole or spot in the skin—so frequently the seat of these tumors—in this situation. Of this, however, she had no knowledge. Its excision was deemed advisable, and was readily consented to by the patient.

Aug. 31st.—Chloroform was administered, and Mr. Paget removed the tumor, with a portion of the skin and subcutaneous fat in which it was embedded. The edges of the wound were brought together by strips of plaster.

On examining the tumor, Mr. Paget pronounced it to be a soft cancerous growth of an epithelial nature. Its dark colour was confined to its superficial surface.

Sept. 6th.—The wound is granulating, and the patient is going on well.

Correspondence.

NEW APPARATUS FOR FRACTURES OF THE INFERIOR EXTREMITIES.

SIR,—If you consider the undermentioned description of a newly-invented apparatus for the cure of fractures of the inferior extremities to be worthy of a place in your excellent journal, I shall feel obliged by your inserting it in an early number.

I have the honour to be, sir,

Your obedient servant.

J. WHEAT D. BROWN, M.R.S.C.E.
House Surgeon and Junior Demonstrator
of Anatomy, London Hospital.

There are few things in surgery, according to my experience, more difficult to accomplish than the cure of an oblique fracture of the femur without deformity of

the limb, because the strong muscles of the thigh contract powerfully, and draw the inferior portion of the broken bone upwards, which necessarily causes a shortening of the limb; and, as compound and comminuted fractures of the thigh are also very difficult to manage, a great many ingenious mechanical contrivances have been used with the view of overcoming the power of the muscles, and of keeping the fractured ends of the bone in apposition. Still, as but few cases of fractured thigh-bones, when consolidation has taken place, are free from some kind of deformity, I have, after bestowing considerable attention on the subject, invented an apparatus by means of which I think that surgeons will succeed with more ease to themselves, and with a greater certainty of curing all kinds of fractures of the thigh without deformity, than by any of the other plans of treatment usually had recourse to.

In describing this new apparatus, I shall, as I proceed, refer to the accompanying drawings of it, which will enable me more clearly to explain its principle and mode of action. It is made of thin sheet iron, formed into the shape of the limb, and extends from near the axilla down to the sole of the foot (see drawing 1, fig. 11). The part that embraces the leg consists of two portions which slide upon each other (fig. 2; see back view, 2 2), and are firmly fixed underneath by means of screws. The lower part has a foot-piece attached to it; and at the place where the heel is to rest, a piece is taken out so as to prevent undue pressure on that part (fig. 3). The upper part

DRAWING 1.

DRAWING 2.

DRAWING 3.

of the leg-piece slides upon the lower portion of the thigh-piece, and is fixed underneath by means of screws. The upper part of the thigh-piece is attached to the hip portion by two hinges, one upon the outer side, the other upon the inner (vide fig. 6 & 6). The hip-piece, which is attached to the thigh portion by means of these hinges, extends by a narrow projecting part half way up the side (fig. 7), into which another part that is made to draw up towards the axilla slides; the hip-piece expands very much just above the crest of the ilium, and passes over towards the opposite hip, in order to support the sacrum behind; and from this point down to the joint it gradually slopes in, so as to leave the perineum free (fig. 6).

This apparatus, as has been shown, consists of four distinct portions; two for the leg; one for the thigh, the upper portion of which, or hip-piece, covers and adapts itself to the formation of the hip and hip-joint, so that by means of the slides the apparatus can be lengthened or shortened, according to the length of the patient's limb. The upper and outer side of the hip-piece that extends upwards receives the fourth piece, which is fixed in its slide by means of a screw, so that this part of the apparatus can also be lengthened or shortened according to circumstances. At the upper part of the fourth piece there are two openings through which a piece of webbing is passed for the purpose of fixing this part of the apparatus to the chest (fig. 9); and this strap is kept in its place by two pieces of tape which cross each other, being fastened before and behind. Immediately below the above-mentioned openings there are two others through which pass the ends of the perineal band, for the purpose of making counter extension (fig. 10). At a short distance lower still are two more openings, one opposite the other, through which a band is passed to fix the pelvis to the apparatus (fig. 11). Immediately below the hip-joint are two other openings, one on each side, through which a strap is passed to fix the upper part of the thigh (fig. 12). Above and below the knee-joint are two more openings, opposite each other, through which straps are passed to fix the limb above and below the knee (figs. 13 and 14); and at the ankle-joint and upper part of the foot-piece are other openings of a similar description, for the purpose of fixing the ankle and toes (figs. 15 and 16).

Before applying the apparatus, a soft cushion, well padded with wool, of the size and shape of the apparatus, but rather broader, is placed in it, or an air cushion of similar shape and size. As soon as one or other of the above cushions has been properly adjusted, the limb is to be put

into the apparatus, and a two-headed roller applied round the ankle, which must first be defended by leather strapping and wool: the perineal band is then to be tightened, and securely fixed, and extension of the limb made, by drawing the leg down, and fixing the foot, by means of the roller, to a projecting handle attached to the foot-piece, which firmly fixes the whole limb. After this has been done, should one end of the bone rise above the other, and the broken limb be found to be shorter than the sound one, all that is required to be done is to loosen the joints of the apparatus, by turning the screws that fix them, and gradually lengthen them until the limb has been sufficiently elongated, when they are again to be fixed by the screws. The transverse straps above described are next to be brought round the limb and firmly fixed, which will necessarily keep the broken ends of the bone in apposition;—indeed, I think it must be evident, after this apparatus has been properly applied, that displacement can hardly take place; because the limb will lie upon, and be supported by, a smooth surface throughout its whole length, from the crest of the ilium to the sole of the foot. The action of the strong muscles situated on the back part of the hip-joint, the extensor muscles of the thigh, the flexors of the leg, and the extensors of the foot, will be overcome, and can hardly, I think, displace the ends of the broken bone: and if pressure be found to be required at any particular point on the anterior part of the thigh, there is no necessity for having recourse to any kind of bandage; all that is requisite to be done is to loosen the belt that is placed above the knee, and the one at the upper part of the thigh; then to place over the point where the pressure is required as many well padded short splints (drawing 2) as may be necessary to support the part, and to fix them by again drawing the above-named straps tight; and, as it is not necessary while doing this to move the apparatus, or in any way to alter the position of the patient, the fractured part of the bone can at all times be examined without the slightest inconvenience, which is a great advantage.

Another important point connected with this apparatus is, that the patient can raise himself up a little in his bed; for, as his body is fixed to the portion above the joint of the apparatus, he is enabled to flex it at this joint, and still there will be kept up sufficient extension, counter extension, and also pressure on the muscles of the hip behind, to prevent the broken ends of the bone from being displaced; whereas, where the common splints are used, however skillfully they may be managed, the efforts of

the patient to raise himself up for the purpose of eating, drinking, &c., too frequently cause displacement of both splints and bone. In cases where the fracture has taken place high up, and the upper portion of the bone is displaced by the action of the psoas and iliacus muscles, the lower portion must be brought into a line with the upper, which can easily be effected by raising the under part of the apparatus, which will bend at the hinge opposite the hip-joint, and still continue to keep up, from behind, a firm pressure upon all the muscles of the hip, thigh, and leg; and as success in the treatment of fractures of the femur depends chiefly upon being able to counteract the action of the muscles, and to keep the limb unmoved until after consolidation of the callus has taken place, I doubt not, for the reasons I have just assigned, that the above apparatus will satisfactorily accomplish those important objects, as has been proved at this hospital in one very severe case of compound comminuted fracture of the thigh-bone, in which, after every other plan of treatment had failed, this apparatus was used with much greater success than could possibly have been expected under the peculiarly unfavourable circumstances of the case: and I cannot allow this opportunity to pass without observing that, in cases where the femur is fractured above, or at its middle, that extension from the lower part of the bone itself may, I think, be advantageously made, through means of this apparatus, by passing round the knee a rather broad, firm, well padded knee-band, to which two short straps, with buckles at their ends, are fixed, one on the outside, the other on the inside of the joint; then, by passing round the outside of the foot-piece, below the projecting handle, the middle of a long leather strap, the ends of which, having been brought up close to the leg as far as the knee-joint, are, as soon as the broken bone has been properly placed, to be pushed through the above-mentioned buckles, drawn tightly, and secured, which, I think, will cause sufficient extension above the knee to prevent the inferior portion of the broken bone from being drawn upwards; and as soon as this has been done, the leg and foot should be extended, and firmly fixed in the apparatus, as above directed. I have not yet had an opportunity of trying this method of treatment, and cannot, therefore, at present speak positively as to its effects; but where the thigh-bone is broken as high up as its middle, it certainly, I must say, does appear to me to be plain, from the construction of the apparatus, that it might, in the manner just described, be so used as to render the risk of after displacement of the ends of the broken

bone but very small; because in this way, if properly managed, extension will necessarily be made and kept up from the lower end of the broken bone itself in a line with the upper portion, the leg and foot being at the same time extended and fixed, as above described, by means of the bandage at the ankle.

In cases where the patella is broken transversely, the apparatus now under consideration will be found to be of great value; for, as it bends at the hip, the limb, when placed in it, may be elevated to the proper height, and, at the same time, the body, by means of the hinge at the hip-joint, can be raised as high as may be requisite, which, in my opinion, is the best position in which a patient with a transverse fracture of the patella can be placed. The apparatus, too, may be used in fractures of the leg; and I shall only add, that it can also be made to answer the purpose of a double-inclined plane for the thigh and leg, by placing a hinge below the knee with a screw (drawing 5), through means of which, and the hinge at the hip, the leg and thigh, when placed in the apparatus, can be bent to, and kept at, any angle that may be required.

London Hospital, September 16, 1856.

TESTIMONIAL TO DR. CONOLLY.

SIR,—The following letter will, I hope, be regarded by you as of sufficient public interest to be allowed insertion in the MEDICAL GAZETTE.

I find by the printed circular that it has been determined to present Dr. Conolly with a Public Testimonial in acknowledgment of his successful efforts to ameliorate the condition and improve the treatment of the insane; and I doubt not that subscriptions ample for the purpose will be raised.

The testimonial considered most appropriate by the Committee is a portrait of Dr. Conolly, to be presented to his family; and an engraving of the same, to be presented to the subscribers. It is on this form of testimonial I wish to remark.

The first object of a testimonial is to do honour to merit; and in many instances this object embraces all that is required to be fulfilled. But in many instances, also, there is another object to be held in view, to confer a benefit as well as an honour upon the meritorious individual or his family: and this is to be accomplished by the form or kind of testimonial.

It has appeared to me that, on several occasions, the Committee authorized to decide upon the form or kind of testimonial have erred, and, instead of conferring an honour and benefit upon the individual

or his family, have rather taken advantage of a good name to promote some local improvement, or to serve some body of men.

In the instance of the late Rev. Canon Tate, his friends and pupils were called upon to do honour to his name by subscribing to rebuild the school-house at Richmond; which was indeed to make use of the esteem and repute in which the Rev. Canon was held, to effect a purpose beneficial to Richmond, while his family, to whose benefit the subscription fund should have been appropriated, were disregarded.

In the instance of Sir Benjamin Brodie, the subscriptions of his friends and admirers were diverted to the founding of a medal for the students at St. George's Hospital; the effect being to benefit the medical staff of the hospital rather than to honour and gratify Sir Benjamin, by presenting to him a testimonial to be handed down with his title as an heirloom to his family.

Had the Rev. Canon Tate bequeathed funds for the rebuilding of the school-house, or had Sir Benjamin Brodie given the medal to the students of St. George's Hospital, the form and kind of memorial would be consistent; but the course adopted leaves the impression of advantage having been taken of a fair name to promote a local interest or gain a private end.

These remarks do not apply to a portrait! Yet it is a question what testimonial would be most beneficial and acceptable to Dr. Conolly.

To determine this, it should be remembered how arduous has been the struggle made by Dr. Conolly to effect the good he has accomplished, and to elevate himself to his present high position: it should be remembered, that the efforts of his professional career (in common with the efforts of every physician) have been not to gain honour only, but to acquire fortune for the advancement of his family in life, and the independence of himself in old age. Would not, therefore, the presentation of a purse, say of a thousand guineas, be the more fitting and substantial testimonial? A portrait is of little value; and, where not only the immediate friends but the public are the subscribers, an engraving is not called for, and will not be coveted.

On the occasion of Dr. Conolly leaving Warwickshire, his friends desired to possess some memorial of him; and a portrait and an engraving, as indicative of personal esteem, were quite in character.

Besides, when I recollect the immense wealth and the famed liberality of this country, and the vast numbers who take a lively interest in the sunderation of the condition of the insane, I cannot but think the presentation of a portrait a reward too

insignificant for the public to bestow. There are many, very many, who would not subscribe to a portrait, who would yet give liberally to a more sterling testimony. I cannot but think that if greater publicity by circular and advertisement were given to the subject of a *pecuniary* testimonial to Dr. Conolly, as a public acknowledgment and reward for his long, zealous, disinterested, and most successful labours, the appeal would be responded to by wealthy philanthropists by subscriptions not of single guineas, but of five, tens, twenties, fifties; and that a fund would be raised worthy of the object and of the public.

Your obedient servant,
M.D., A SUBSCRIBER.

Bath, Sept. 14, 1850.

TREATMENT OF ANASARCA BY INCISION— THE CLAIMS OF MEAD AND LOMBARD.

SIR,—It would be a difficult and profitless task to have to determine the title which every modern writer has to originality; but, as a curious instance of the credit which some gain for that which is not their own, I may quote a sentence from Dr. Todd's lecture on Cardiac Dropsy in this week's Gazette:—"There is another method," says he, "of relieving the anasarcaous legs, lately proposed by Lombard of Geneva. Instead of pricking the legs at various points with a needle, he advises to make a single incision above the inner malleolus, or in some other convenient position (not too near a vein or artery), cutting through the skin and subcutaneous tissue down to the fascia. The length of the incision may be half an inch or an inch; and the rapid flow of water that these incisions admit of, is further encouraged if the patient sits on the side of the bed a certain time during the day with his feet placed in a tub." The plan of treating anasarca here attributed to Lombard is minutely described by Mead in his *Precepta Medica*, and illustrated by a case. He says, "*In leucoplegmatia invisio in tibia parte inferiore feri debet duobus super talum digitis ita ut vulnus ad cellulosa membranam nec ultra penetret quo per dies aliquot frequens humor feratur, crus autem interea fovere oportet decocto herbarum emollientium et calidarum adjecto spiritu vinoso cui addita sit camphora. At mirum tamen est quantam aquosi latidis sic effusi jacturam cum levamine ferant interdum hydro-pici. Cuius rei singulare testimonium proferre libet femina generosa, mihi cognata anasarca fere quinquaginta corpore firmo satia et robusto hydropice intercute et ascite laborabat ita in immensum tandem ventre distento ut decumbens omnis tam grave ferro nequirit. Cum de vita fere desperaretur*

unicam spem salutis eamque dubiam in humoris e talo emissionis superesse dixi. Illa autem strenue repugnabat. At precibus denum amicorum victa cessit itaque ex vulniculo in utroque crure eo modo quem exposui facto profluxit decem continuis diebus aqua ad congruam mensuram minimum quotidie." He goes on to say, that by tonics and diuretics the health of his patient became re-established, and that she remained well for five years.

It is not my purpose to discuss the treatment of anasarca, but to transfer from Lombard to our own Mead, all the credit this method may deserve.

I am, sir,

Yours respectfully,

WILLIAM GULL, M.D.

Gay's Hospital, Sept. 21, 1850.

MEASLES OCCURRING SPORADICALLY IN NEW-BORN CHILDREN.

SIR,—In the several discussions that have taken place regarding contagion in cholera, the fact which has always been considered most decisive upon the negative side of the question has been the demonstration of a genuine case where contagion cannot be traced, or scarcely conceived possible. On such occasions the difficulty of showing at all times the source of contagion in other universally recognised contagious diseases is but rarely adverted to. Let any one, however, who is interested in this subject, endeavour to determine the immediate origin of all the exanthematous fevers with which he may meet, and the links that connect case with case will present anything but an unbroken chain. My own experience as regards measles, scarlet fever, and small-pox, exhibits the difficulties of the contagious theory just as remarkable in respect to them as to pestilential cholera. Some of your readers may feel interested in the subjoined particulars, which exemplify in a striking manner the development of measles, complicating our ordinary notions very much on the propagation of this disease, and possessing, I conceive, considerable importance in their bearings upon the general subject of contagion:—

Mrs. E. gave birth to her first child on the 25th of July, 1847, attended by a friend on my account, during my own absence from home. I saw both mother and child upon my return in a few days, and they seemed doing well. Having taken my leave of the patient in about ten days from her labour, I was summoned to see the infant child in three or four days afterwards, and found it covered with measles, attended by fever, and having been preceded by the ordinary premonitory symptoms of coryza and cough. The symptoms declined in

the usual way, and in about a week the child was well. I neither saw, nor could hear of, any other case from which it could have been taken. The mother, intending a probable explanation of the phenomenon, stated that, according to the statements of her mother, she and a twin sister had measles also when a fortnight old.

On the 12th June, 1849, Mrs. E. gave birth to a second child. She did well, and I ceased to visit her at the expiration of about a week.

On being summoned to attend another member of the family some months afterwards, I was informed that the second child had had measles at the same period after birth, and exactly under the same circumstances, as in the former instance. All the inquiries I could make led to a conviction upon my part of the accuracy of the statements that were made. It had not been considered necessary to call in medical aid.

During the present year Mrs. E. again became pregnant, and I was once more engaged to attend her. She was confined on the 31st ult. under circumstances quite favourable. I was naturally curious to know what would happen with the child, when ten or twelve days old, and continued my own personal observation. Measles again became developed, accompanied and preceded by slight fever, with mucous irritation of the air passages. The case this time was but slight, yet it was unequivocal. The infant is now well again. Measles do not prevail in the neighbourhood; nor am I aware of any case from which the contagion could have been received.

I have mentioned the above circumstances to several medical friends, but have heard of no parallel experience; neither have I in books discovered records of anything of the kind.

The cases are curious at least; but in what point of view are they to be regarded *pathologically*? Were they true measles? Or does the debris of some *rubeolous* poison yet lurk in the maternal system, transmissible, like the syphilitic poison, to the fetus in utero? I do not myself offer any speculation.

Such instances, however, should be kept in mind when, from difficulty and impossibility of tracing contagion, we are prompted to reject altogether the idea of certain diseases being communicable.

I remain, sir,

Your obedient servant,

DANIEL NOBLE.

Manchester, Sept. 15, 1850.

General Intelligence.

THE INCORPORATION OF MEDICAL PRACTITIONERS.

Copy of Report of the General Committee of the National Institute.

THE Committee, in accordance with the resolution of the Council agreed to at the last meeting, took immediate steps to place the Bill for the Incorporation of the General Practitioners in the hands of James Wyld, Esq. M.P., in order that it might be presented to Parliament as speedily as possible; and they are enabled to report that the bill was laid on the table of the House of Commons on the 29th of July last, with an understanding between that gentleman and the Government that it should not be proceeded with during the then session of parliament: the bill has since been printed by order of the House.

With the view of securing future co-operation in support of the proposed measure during the ensuing session of parliament, and also of increasing the pecuniary resources of the Institute, the Committee have deemed it expedient to forward the following note to those who, although members of the Institute, are in favour of the incorporation of the general practitioners:—

The National Institute of Medicine, Surgery, and Midwifery.

4, Hanover Square,
August 20th, 1830.

SIR,—I am directed by the Council of the National Institute to inform you that the Bill framed for the Incorporation of the General Practitioners has been presented to the House of Commons by Jas. Wyld, Esq. and Colonel Thompson, and printed by order of the House, and may be obtained at the office for parliamentary documents, Great Turnstile, Holborn. Should you wish for a copy I shall be happy to forward one to you. The Council are most anxious to afford those gentlemen who favour the measure every information on the subject, in the hope that they will use their best endeavours to disabuse the minds of such of their professional friends as may entertain groundless fears and apprehensions with reference to the proposed measure, and with the view, also, to secure their co-operation and support during the ensuing session of parliament.

I am desired further to inform you that the introduction of the bill into parliament, and the means necessary to be adopted by the Council to facilitate its future progress, will be attended with considerable expense;

the Council of the National Institute therefore feel that at the present period they are fully justified in placing most prominently before the profession the subjoined copy of a resolution unanimously agreed to at a general meeting held at the Hanover Square Rooms:—

Copy of Resolution.

"That the interests of the profession at large at the present moment demand that unanimous and cordial support be given to the Council of the National Institute, for the purpose of maintaining, strengthening, and extending the present organization of the general practitioners in medicine, surgery, and midwifery; and that a voluntary subscription-book be forthwith opened for the purpose of collecting funds to enable the Council of the National Institute to carry out in full the measures now adopted by this meeting."

The Council cannot but entertain the greatest confidence that the just appeal contained in this resolution will be cordially responded to by those who advocate the independent incorporation of the general practitioners, especially by those who have evinced in the schedules returned their desire to accomplish this great object.—I have the honour to be, sir,

Your most obedient servant,
HERBERT WILLIAMS,
Secretary pro tem.

Subscriptions of any amount may be forwarded by post-office orders, or otherwise, either to Edward Tegart, Esq. or John Dodd, Esq., Treasurers; or, if by post-office order, made payable at the Post Office, Old Cavendish Street.

Several letters of a favourable character have already been received in reply to this communication: but as its issue is of recent date, the Committee are unable to state how far the application may prove generally successful.

Since the last meeting of the Council the Committee have had occasion to consider the suggestions contained in the letter recently transmitted by the Society of Apothecaries to Sir George Grey for the purpose of effecting an alteration of the Act of 1815; and they have in consequence felt it their duty to forward to the Society a resolution condemnatory of the course therein suggested, it being not only inconsistent with the principles they have hitherto advocated conjointly with the National Institute, but as tending to prejudice permanently the interests of the general practitioner:—

Copy of the Resolution.

"That this Committee having considered the propositions contained in the letter

from the Society of Apothecaries to the Right Honourable Sir George Grey, Bart. for altering the Act of 1815, hereby declare that they cannot support any scheme for regulating the education and conducting the examinations of the general practitioners in medicine, surgery, and midwifery, which is incomplete, or which does not embrace all the branches of education and practice necessary for the efficient performance of the duties of general practice. That in particular the Committee repudiate the remodelling of either of the existing Institutions (as they have hitherto the establishment of any new institution) that is not based upon the union of medicine and surgery, and which, in the education and examination for admission into such institution (which is also intended to confer a title to practise) does not embrace all the branches of both medicine and surgery.

"That the want of proper authority to examine in surgery has at all times since the Act of 1815 operated prejudicially upon the examinations instituted by the Society of Apothecaries; and that this Committee unequivocally condemns any proposition to alter that Act which does not embrace an amendment in this essential point. That the union of medicine and surgery has been the fundamental principle of the National Association and of the National Institute, and has been consistently adhered to throughout; and that, without questioning the right of the existing institutions to retain their special character, the Committee resolves to adhere to this principle, in reference to the education and qualification of the general practitioners, as essential to any measure of medical reform."

An acknowledgment only of the receipt of this resolution has as yet been received from the Society of Apothecaries.

At the annual general meeting of the members of the Institute, which took place on the 14th of August last, the following resolution was unanimously adopted:—

"That this meeting, deeming it inexpedient at the present time to proceed to the election of a new executive, do now adjourn until the second Wednesday in December, and that the present Council be requested to continue to conduct the affairs of the Institute in the interim."

The Committee hope that at the period mentioned in this resolution circumstances may enable the Council to suggest to their constituents and the profession generally some decisive course of action for their adoption, in order to sustain, during the ensuing session of Parliament, those principles for which they have so long contended.

On taking a retrospective view of the

proceedings of the National Institute, and the present state of the medical reform question, the Committee reiterate the sentiments which were specially addressed to the Shropshire Medical Association in their Report of August 9th, 1848. In commenting on the petition forwarded by that body to the House of Commons, the Council of the Institute stated, on the part of the General Practitioners of England, that, if the object of the petitioners could be obtained—viz., the concentration of the great body of the profession in the College of Surgeons, with a ten years' franchise, the right of voting carrying the right of holding offices of honour and distinction in the College, under proper limitations, but with no distinction as to whether the individual practises as a surgeon purely considered, or as a general practitioner—by which modification of the constitution of the College of Surgeons the general practitioners would have an efficient control over their own affairs, and a direct influence over the examinations of their own class—that their demands would be satisfied.

The foregoing principles have invariably been advocated by the Institute upon every occasion, so far as they relate to the College of Surgeons; and the Committee propose on a future occasion to lay before the profession their opinions on the scheme enunciated by the Council of the Royal College of Surgeons in their last communication to the Right Honourable Sir George Grey Bart.

THE IMPORTANCE OF LIFE INSURANCE TO MEDICAL PRACTITIONERS.

THE destitution in which so many of our brethren die and leave their families, affords scope for the utmost commiseration and regret. Some, it is true, suffer from the untoward urgency of circumstances, but others go on from day to day, without employing the means which lie at their disposal, to avert the else certain impoverishment that awaits wife and child, and perchance other dear dependents. The man must be wanting in natural affection or common sense, who neglects to provide for those whose welfare God has lodged in his hands. Who has a right to contract marriage, without discharging, so far as in him lies, the sacred obligations which it entails? There have been those who lived in unscrupulous profusion, whose families, nevertheless, it has devolved on the public to support. It is a common feeling with medical men, that they must "keep up an appearance;" and to this they too often sacrifice, or hopelessly procrastinate, the yet more insuperable obligation of making a provision for their families. How much better than this unwarrantable ostentation would

be the division of the daily receipts, half for immediate sustenance, and half for prospective requirements. If a man cannot or will not save, he should either abandon his profession, or at least not implicate others in his improvidence. Considering the exigencies and inevitable uncertainty of human life—medical life in particular—no one can deny the necessity, no one contest the efficacy, of saving. That admirable invention of modern times, life assurance, enables every man to compass a provision in reversion, almost out of hand. For the yearly outlay of twenty pounds, a practitioner turned twenty-six can secure a thousand pounds, with additions, payable were his decease there and then to ensue the very instant after his policy was signed. For a reasonable increase, the policy, for that or any other given sum, may be paid up in ten, fifteen, or twenty years; securing, as it were, in addition, a reversionary annuity for his declining years, or those other purposes which family requirements do not fail to suggest. I invite every member of the profession, if his life be not already assured, or his independence otherwise secured, in place of an annual guinea to a medical fund, to hand over his guinea, if no more, to an insurance company. For this slender sum a man at the age above noted will certainly secure to his family some fifty pounds at the period of his decease. The Irish Benevolent Fund, by its last audit, had but two hundred and fifty pounds at its disposal—a sum manifestly inadequate to meet the numerous applications (those of sixty-three heads of families in all) which were made to it. What was this among so many? There can be no possible reason why all medical men should not thus avail themselves of the benefits of assurance; and little doubt, I think, can remain upon the mind as to which procedure is the more eligible—which more conformable to prudence and real charity to survivors. These remarks apply, *mutatis mutandis*, as much to Britain as to Ireland. I am anxious to impress it on the members of our noble profession, not to rely on the slender contingency of a benevolent fund, but upon their own right arms. I would urge all to appreciate the inestimable blessings of life assurance, to practise it themselves, and impress it on those within the sphere of their influence; and I would respectfully solicit the press to yield these my well-meant, and I trust useful, exhortations, a wide-spread diffusion.

HENRY M'CORMAC, M.D.

THE CHOLERA AT VIENNA.

The cholera is very prevalent among the workmen on the railway of Mount Soem-

mering. In Vienna itself it appears to be stationary. Since its reappearance there have been 1019 cases, of which 422 proved fatal, 432 recovered, and 165 were still under treatment. At Pesth, in Hungary, the cholera is still on the increase; but it is particularly in a small town of Moravia, Grosshöflein, that the disease is producing the greatest ravages. In two days it carried off 68 persons—i. e., about 5 per cent. of the population, which does not exceed 1300 persons.

THE CHOLERA AT MALTA AND IN THE IONIAN ISLANDS.

THE intelligence from Malta, coming down to as late a date as the 15th instant, continues very unsatisfactory. The cholera, which in the early part of September was materially on the decline in the island, has subsequently been very fluctuating, as will be seen in the official reports below, which embrace only the civil population; and the disease is no longer, as at first, confined to the lower and indigent classes. According to these returns, there were, on the 1st of September, 10 attacks and 14 deaths; 2d, 13 attacks and 13 deaths; 3d, 7 attacks and 8 deaths; 4th, 19 attacks and 12 deaths; 5th, 16 attacks and 8 deaths; 6th, 16 attacks and 9 deaths; 7th, 36 attacks and 18 deaths; 8th, 13 attacks and 14 deaths; 9th, 49 attacks and 21 deaths; 10th, 20 attacks and 21 deaths; 11th, 32 attacks and 16 deaths; 12th, 20 attacks and 17 deaths; 13th, 17 attacks and 8 deaths; 14th, 10 attacks and 10 deaths; which, added to former reports since the 13th of June, bring up the total attacks to 2,813, and the deaths to 1,502. Among the military there are only occasional cases, confined entirely to the ranks; but the Bellerophon ship of the line, which came in from the squadron then in the offing, on the 9th of September, to fill up water and provisions before leaving for England to be paid off, had four seamen attacked on the 12th, and 16 more on the 13th, several of whom died within a few hours after being attacked, whereupon the Rear-Admiral-Superintendent of Malta-yard, as senior officer, ordered the ship immediately to sea. Vice-Admiral Sir William Parker, accompanied by his family, left Malta in the Queen, with the Terrible in company, on the 8th. The Board of Health at Malta has reduced the quarantine on arrivals from Marseilles to nine days for steam packets and twelve for sailing ships. We learn, *via* Malta, that the cholera had manifested itself at Cephalonia on the 21st of August, and up to the 4th of September there had been 70 cases, of which 34 had been fatal. A report had reached Malta that a suspicious case had

occurred at Zante, Corfu, and the other islands of the Ionian states which were free, had placed Cephalonia under a quarantine of twelve days, which Malta had also adopted. Recent letters from Tripoli and Tunia received at Malta report the former place to be still seriously infected with cholera, but at the latter it had nearly subsided, and those who fled, panic-stricken, had to Malta, Leghorn, and other parts, were returning to their homes.

SICKNESS AMONG THE ENGLISH TROOPS AT HONG KONG, CHINA.

INTELLIGENCE from Hong Kong, dated July 24, states that sickness among the troops has been on the increase: as many as 160 men have been in the hospital at one time, and about 35 have died of fever. This happened when there was no unusual sickness among either the community, or the Government police force. In 1848 the 95th Regiment, from illness and the number in hospital, was declared unfit for duty, and about 100 were carried off in a short space of time. Some attribute the cause of this to the unhealthy position of the barracks, occasioned chiefly by the nature of the ground in the rear. It is more likely, however, to proceed from the crowded state of the rooms occupied by the men, and at night in particular, their beds being only six inches apart—as close, we understand, as they are in an European and cold climate.

Good ventilation and as much air as possible is considered a *desideratum*, and necessary by all in an eastern climate; but the soldiers have been deprived of this necessary of life; air is excluded, and in consequence an obnoxious and a poisonous atmosphere is generated. In the hospital the same evils exist; and we have heard those qualified to judge express an opinion that healthy persons exposed for a short time to the atmosphere that exists in these places, would soon be affected and carried off, as the unfortunate troops are.

OBSTACLES TO THE DIFFUSION OF VACCINATION.

ALTHOUGH the poor are now vaccinated gratuitously, and ample means are provided by the Poor-law Board for carrying out the intentions of the legislature, an unaccountable prejudice still exists against vaccination. Some of the objections to it are excuses for negligence; others are based on a sort of fatalism; but others, again, amount to almost criminal neglect. The Registrar for Nottingham states that a woman in his district who had lost a child, by disease, assured him that she would rather lose half a dozen children by it, than *fly in the face of Providence in having one vaccinated!*

LIST OF ASSURANCE OFFICES WHICH RECOGNISE THE PRINCIPLE OF REMUNERATION TO ALL MEDICAL REFEREES.

[We copy the following list from a contemporary:—]

Architects, 69, Lombard Street, London.
 Britannia, 1, Princes Street, Bank, London.
 British Mutual, 17, New Bridge Street, Blackfriars.
 Church of England, Lothbury.
 Commercial, 112, Cheapside, London.
 East of Scotland, 1, Bank Street, Dundee.
 Engineers, Masonic, and Universal, 345, Strand.
 English and Scottish Law, 12, Waterloo Place, London.
 English Widows' Fund, 67, Fleet Street.
 General and Mining, 4, Bridge Street, Blackfriars.
 General Benefit, 4, Farringdon Street.
 Great Britain, Waterloo Place, and King-William Street.
 Indian and London, King-William Street, and 14, Waterloo Place.
 Industrial and General, 2, Waterloo Place, Pall Mall.
 Kent Mutual, High Street, Rochester.
 Kent Mutual Life Assurance Society, 6, Old Jewry, London.
 Leeds and Yorkshire, Commercial Buildings, Leeds.
 Legal and Commercial, 73, Cheapside.
 London Indisputable, 81, Lombard Street.
 London Mutual Life, 63, Moorgate Street, City.
 London and Provincial, 39, Nicholas Lane.
 Medical, Legal, and General, 126, Strand.
 Medical, Invalid, and General, 25, Pall Mall.
 Metropolitan and General, 27, Regent Street, Waterloo Place.
 Mitre, 23, Pall Mall.
 National Loan Fund, Cornhill.
 National Mercantile, Poultry, Mansion House.
 New Equitable Assurance Company, 450, West Strand.
 North of England, 11, Cheapside, London, and Old Haymarket, Sheffield.
 Professional, 76, Cheapside.
 Prudential, 14, Chatham Place.
 Royal, Royal Insurance Buildings, Liverpool.
 Royal Exchange, Royal Exchange.
 Royal Farmers and General, 346, Strand.
 Scottish Equitable, 26, St. Andrew's Sq., Edinburgh.
 Sovereign, 5, St. James's Street.
 Solicitors and General, 57, Chancery Lane.
 Star, 44, Moorgate Street.
 Westminster and General, 27, King Street, Covent Garden.
 Yorkshire, York..

MEDICAL SOCIETY OF LONDON.

At a meeting of the Council of this Society, held on the 19th inst., the following gentlemen were elected members of the Sectional Committees on Medicine, Surgery, and Midwifery:—

Medicine.—Dr. Webster; Dr. Sibson; Dr. J. R. Bennett; Dr. Copland; Dr. Babington; Dr. Garrod; Dr. Lankester.

Surgery.—Mr. Hancock; Mr. Dendy; Mr. Pilcher; Mr. Erichsen; Mr. Hird; Mr. Hilton; Mr. Toyne.

Midwifery.—Dr. Murphy; Dr. Chowne; Mr. Greenhalgh; Dr. Merriman; Dr. Smiles; Dr. Waller; Dr. Lever.

MEDICAL EDUCATION IN SPAIN.

DURING the year just elapsed there were 19681 students in the Colleges and Universities of Spain. These were distributed in the following order:—

1.	Class of Philosophy	13453
2.	Law	3750
3.	Medicine	1646
4.	Theology	1157
5.	Pharmacy	539
6.	Surgery	144

OBITUARY.

DR. JOHN MARSHALL.

At Falmouth, on the 30th ult., aged 67 years, John Marshall, M.D., for many years a surgeon in the Hon. E. India Company's Service, and late member of the Medical Board, Calcutta, and Physician-General of the Bengal Presidency.

DR. W. BAKER.

On the 30th ult., at Derby, William Baker, M.D., aged 60.

DR. FOGO.

On the 18th inst., at Tiverton, Devon, Thomas Macmillan Fogo, Esq., M.D., late of the Royal Artillery.

M. PREVOST.

It is with regret we announce the death of this eminent chemical philosopher, which took place recently at Geneva. M. Prevost had acquired a high reputation by the researches which he made conjointly with M. Dumas. He was in his 60th year.

DR. WILSON.

At Lahuan, in the Eastern Archipelago, from the effects of a sun-stroke, Dr. Wilson.

Selections from Journals.

A SURGICAL CURIOSITY.—A GOOSE'S LARYNX REMOVED BY TRACHEOTOMY FROM THE LARYNX OF A CHILD. BY PROFESSOR BUROW, KÖNIGSBERG.

DR. BUROW states that a favourite plaything with children in his country is the larynx of a freshly killed goose. It is removed with ten or twelve rings of the trachea, and forms a sort of musical (?) toy, when blown, giving out the cry of the goose nearly the same as during life. A boy, twelve years of age, was amusing himself in this manner, when he suddenly coughed, and the goose's larynx was immediately and violently drawn into his own larynx. He was seized with great difficulty of breathing, which, however, soon in some degree abated. When seen by Dr. Burow, eighteen hours after the accident, he was still suffering distress in his breathing; his countenance heavy; his face congested, and covered with perspiration. Each inspiration was effected by a spasmodic action of the muscles of the neck, and was accompanied by a clear shrill cry like that of a goose. However improbable it seemed, from the relative size of the parts, it was not possible to come to any other diagnosis than that the goose's larynx was impacted in the glottis of the child. The danger with which life was threatened determined Dr. Burow on having immediate recourse to tracheotomy.

When the trachea was opened, it was with the greatest difficulty that the object could be reached by instruments. The patient's trachea was completely filled with mucus, besides which the irritation of the instrument induced a violent fit of coughing, which elevated the larynx out of reach. At last, three rings of the trachea were brought away by the forceps, thus confirming the diagnosis. After several fruitless efforts, the whole of the goose's larynx was removed through the wound in the child's trachea. The patient recovered rapidly from the effects of the operation.

This case was so remarkable in itself, and seemed so improbable, that Dr. Burow, fearing his statement of the case would scarcely be credited, took the precaution of having twelve of his pupils present to witness the operation. — *Casper's Wochenschrift*.

X

MICROSCOPIC EXAMINATION OF THE DISCHARGES FROM THE BOWELS IN CHOLERA.

DR. R. S. HOLMES, of St. Louis, says:—I have examined (microscopically) the discharges from the bowels in six cases

of cholera, and have found the cells of cryptogami in a greater or less degree in four of these cases, and *vibriones* very abundantly in one. The theory I think amounts to nothing. I have found in flour *every one* of the forms of cryptogami that I have been able to discover in cholera cells; one has a peculiar shape, which I have not seen described. I have had a bottle of flour and water on my table for some months, and I am confident I could show in the course of a few days every one of the forms of vegetable growth in it that are seen in cholera discharges, by a Ross one-eighth lens; I say in a few days, for these cells vary in the flour, and are sometimes not to be seen: the cell of the mould of flour precisely resembles that of the smallest of the cholera cells, which is not more than the ¹³⁰⁰⁰th of an inch in diameter, although the peculiar *cholera cell*, so called, seems to have been limited by the English investigators to a much larger cell, with buds upon it.

I may mention that I discovered distinct crystals, having the exact forms of those of lithic acid, in one case where there was suppression of urine.—*American Journal of the Medical Sciences*, July 1850.

NOTICES TO CORRESPONDENTS.

Troviamo tanta difficoltà nel fare cambio dei giornali, coi nostri contemporanei italiani, che siamo costretti a ricorrere la proposizione contenuta nella lettera del Dottore Nannini, di Venezia.

The papers on the Walker Testimonial fund shall receive our attention.

Mr. C. R. Walsh's communication shall be noticed next week.

The contributions of Mr. Lonsdale and Mr. Kingston will be published in the following number.

CORRECTION.—In Mr. Gallwey's paper, last No., page 494, col. 1, line 11, for "Clinical," read "Chemical."

Lectures.

COURSE OF LECTURES
ON
DISEASES OF THE HEART.

*Delivered at St. Vincent's Hospital during the
Session 1849-50.*

By O'BRYEN BELLINGHAM, M.D.

Fellow of, and Member of the Court of Examiners
of, the Royal College of Surgeons in Ireland, and
one of the Medical Officers of the Hospital.

LECTURE XII.

EXAMINATION OF THE HEART IN DISEASE,
(continued).

General signs of cardiac disease—Countenance in heart disease—Position of the patient—Palpitation—Palpitation depending upon organic disease—Palpitation independent of organic disease of the heart—Characters by which the palpitation depending upon organic disease of the heart is distinguished from that which occurs independent of organic disease—Immediate cause of palpitation—Influence of the coronary circulation.

General signs of heart disease.

THE general signs of the advanced stage of cardiac disease have considerable similarity, and the symptoms most generally present are common to several diseased conditions of the heart. In the majority of cases they have their origin in some impediment to the free passage of the blood through the orifices of the left side of the heart, by which the circulation through the heart, or through the lungs, or through both, is impeded.

Disease of the heart may lead to disease of the lungs, and *vice versa*. In a healthy condition of the parts there is a perfect equilibrium between the development and the capacity of the two organs: the exact amount of blood is transmitted by the right ventricle to the lungs, which, in the latter organs, can be converted into arterial blood; and the exact amount of blood is returned by the pulmonary veins, which can pass freely through the left chambers of the heart. But, if this equilibrium is disturbed; if the pulmonary circulation is obstructed, owing to disease in the lungs, bronchial tubes, or pleura, the right auricle and ventricle become distended, and eventually, if the cause continues in action, dilated or hypertrophied. If, again, there is any impediment to the free passage of the blood through the left side of the heart,

congestion of the lungs, as a natural consequence, ensues; œdema follows, then hæmoptysis or pulmonary apoplexy. The effect of the obstruction of the pulmonary circulation extends to the right side of the heart; its cavities become distended, then dilated, or their walls may become hypertrophied. The great venous trunks not being able to empty themselves, become distended, and the whole venous system congested: hence the lividity of the face and extremities, the engorgement of the lungs, liver, kidneys, and other abdominal viscera, which is partly relieved by the escape of the serum of the blood into the cellular tissue of the extremities, giving rise to anasarca; or into that of the lungs, causing œdema pulmonum; partly by its effusion into the abdomen or thorax, constituting ascites or hydrothorax; and sometimes by the escape of the blood itself upon the congested mucous surfaces, giving rise to epistaxis, hæmoptysis, &c.; or into the pulmonary tissue itself, constituting the state with which we are familiar as pulmonary apoplexy.

The general symptoms of the advanced stage of cardiac disease are pretty constant; while those of its early stage vary as the disease is acute or chronic: they vary likewise according to its nature, and to the parts of the heart engaged. Thus, while in the early stage of the *chronic* forms of disease there is scarcely anything characteristic in the symptoms, those which accompany the early stage of *acute* diseases of the organ are usually very well marked.

Among the general symptoms of heart disease, palpitation is usually one of the first which attracts attention. More or less dyspnoea is generally present at the same time, which may or may not be accompanied by cough, or by pain in the region of the heart: the pulse, likewise, sometimes exhibits diagnostic characters. When the disease has lasted for a longer time, or when obstruction to the pulmonary or the general circulation has set in, other symptoms are usually superadded; signs of congestion of the lungs, of the liver, kidneys, or gastro-intestinal mucous membrane, make their appearance. Orthopnoea supervenes upon the dyspnoea, and the over-loaded or over-distended vessels are relieved in part by the escape of the serum of the blood into the general cellular tissue, or into the serous cavities; or sometimes by the escape of the blood itself upon some of the mucous surfaces, or into the pulmonary tissue.

Before entering upon the consideration of those symptoms it may be well to delay for a moment, to consider whether there is anything in the expression or character of the countenance of a patient labouring

under heart disease, or in the position which he assumes, from which information as to its nature may be gathered. In the acute inflammatory affections of the investing or lining membrane of the heart, information may not unfrequently be obtained by attention to these particulars. In the chronic forms of disease nothing is to be learned from them as long as the disease is recent; but when the disease is advanced they are sometimes sufficiently characteristic. Before the discovery of auscultation and percussion, and before diseases of the heart could consequently be diagnosed with certainty, these points received a much larger share of the attention of practitioners than at the present day: they are, however, of sufficient importance to deserve a short notice.

Countenance in Heart Disease.

In the *acute* inflammatory affections of the lining or investing membrane of the heart the countenance early acquires an anxious and depressed character: indeed, it is often so marked as immediately to attract attention; and from it alone the practitioner has been induced to institute a minute examination into the condition of the central organ of the circulation, although the patient made no complaint of any symptom referable to it. This applies particularly to cases of acute rheumatism, in which the articular inflammation comes to be complicated with pericarditis, or endocarditis, or both. The characteristic expression of the countenance in this and similar affections is explained by the sympathy which subsists between the respiratory nerves of the face and the nerves of the heart.

In the *chronic* forms of cardiac disease little is to be learned at first, either from the expression of the countenance, or from the character of the individual features: in the advanced stage, however, the countenance becomes sometimes almost pathognomonic. Thus, in cases where the pulmonary circulation has been long impeded, the venous system throughout the body becomes congested, the capillaries injected, the extremities swollen and cold, and the nails assume a violet hue. The face becomes puffed, tumid, or bloated, the eyes suffused, the lips and cheeks purple, and the respiration hurried and laborious. On the other hand, it not unfrequently happens that, in an equally advanced stage of cardiac disease, there is neither œdema or swelling of the extremities; the face, instead of being bloated, livid, and purple, is extremely pale, haggard, contracted, and expressive of intense distress. The dyspnoea occurs in fits, during which the respiration is gasping; there is a painful sense

of impending dissolution, or the patient utters exclamations of pain, which is referred to the precordial region, or which shoots from the region of the heart to the spine, or scapula, and extends down the arm.

Corvisart* first made the remark, that in persons of the lymphatic temperament the face, instead of assuming a purple tint, becomes more pale than natural in the advanced stage of cardiac disease. Dr. Hope repeats the same remark: "In persons of the sanguine temperament (he observes) who are naturally florid, the lips and cheeks often become injected, and the countenance bloated; while in individuals of the lymphatic temperament, who are naturally pale, it usually becomes still more so." It appears to me, however, that the original complexion of the sufferer is not necessarily the cause of this difference; but that it depends rather upon the nature of the organic disease of the heart under which the patient labours, and whether this has, or has not occasioned congestion of the lungs. Thus, when it consists in a very contracted state of the mitral orifice, with hypertrophy and dilatation of the right ventricle, in which congestion of the lungs is a common result, the face will be congested and bloated, the lips and cheeks purple, and the lower extremities livid and anasarcaous. On the other hand, in cases of disease of the aortic orifice, or its valves, permitting regurgitation into the left ventricle, in which congestion of the lungs does not necessarily occur, the face is not bloated, the lips and cheeks are not purple, and the extremities are not livid or anasarcaous; but the face becomes very pale, and the countenance anxious, and expressive of severe suffering.

When congestion of the lungs is combined with congestion of the *liver*, the complexion, as Dr. Budd† remarks, "becomes purplish, and at the same time *sallow*." "As the blood, when its passage through the lungs is impeded, is imperfectly *decarbonized*, and gives a purplish colour to the face; so, when its course through the liver is impeded, the blood is not completely freed from the principles of bile, and the countenance acquires a slightly jaundiced or *sallow tint*." This had not escaped the observation of Dr. Bright, who remarks: "When obstruction takes place to the circulation through the chest, but more particularly when the heart becomes over-distended with blood, we observe the countenance gradually assume a dingy aspect, in which the purple suffusion of carbonized blood is mingled with the

* Essai sur le Maladies du Cœur.

† On Diseases of the Liver.

yellow tint of slight jaundice; the conjunctiva is more decidedly tinged, and, if the disease continues long, sometimes completely prevails over the purple tint."

A prominence of the eye-balls, giving the eyes a peculiar staring appearance, as if they were larger than natural, or as if they were protruded forward, has been noticed in a few instances in connection with cardiac disease, or with symptoms simulating it, of which the most prominent was palpitation. It coincided in the majority of cases with an enlargement of the thyroid gland. The subjects were females, often of an hysterical habit; and the attacks of palpitation in some instances were prolonged and severe. Dr. Graves* first called attention to it, and subsequently Dr. Macdonnell published some cases. It appears to have a doubtful connection with cardiac disease. In one case, where the subject of it was an extern patient of the hospital, she had continued for several years much in the same state. In another, who presented the same peculiar appearance of the eyes, but without any enlargement of the thyroid body, and who died in the hospital, a small tumor, growing from the dura mater, was found on a post-mortem examination.

Posture of the Patient.

In the early stage of the chronic forms of cardiac disease nothing is to be learned either from the position of the patient, or from the posture which he assumes. He is usually able to rest in the horizontal posture, and seldom finds greater difficulty in lying upon one side than the other; sometimes he prefers the supine posture: frequently it is with great reluctance that he remains in bed.

In acute affections, more particularly in that form of pericarditis where a large amount of fluid is rapidly effused into the pericardial sac, the patient is quite unable to lie down, or to obtain rest in the horizontal posture. Sometimes the restlessness is so extreme that he cannot remain for more a few minutes in any one position, and he is continually changing it: at others he obtains partial relief only in one particular posture, any deviation from which is sure to add considerably to the dyspnoea and distress.

In the advanced stages of valvular disease, when the circulation through the lungs becomes greatly impeded, or when fluid is effused into one or both pleural cavities, the patient cannot lie down; he must have the head and chest elevated, or he is unable to remain in bed, and is forced to preserve the sitting posture. In extreme

cases he is often only able to snatch momentary rest by leaning forward, and resting his head upon his knees, or upon a table. Sometimes the dyspnoea is so extreme that he obtains ease only by lying on his face: this, however, is more frequently observed in aneurism of the aorta pressing upon the trachea than in organic disease of the heart.

When, in addition, effusion to a considerable amount exists in the peritoneal cavity, or when the lower extremities have become much swollen, the position of the patient will be influenced in some measure by these complications. I have seen the dyspnoea aggravated in a remarkable degree by merely bringing the anasarcoous lower extremities to the same level with the body, and the patient could not rest unless they hung down by the side of the bed. In many such cases, indeed, the patient refuses to remain in bed, and sits constantly in a chair.

In other instances, where there is neither anasarca of the lower extremities nor ascites, but where pain and dyspnoea are the most prominent symptoms, and where the dyspnoea occurs in paroxysms of extreme severity, the position which the patient assumes in the paroxysm is peculiar: he sometimes seizes upon some fixed object against which he strongly presses the sternum; or he fixes the arms firmly, so as to call every muscle of inspiration into action; or he writhes about, and almost screams with agony. A patient was in hospital some time since who, during the paroxysms, was unable to obtain ease in any position but sitting upon the ground with the back firmly pressed against the wall. Dr. Hope has drawn a vivid picture of an aggravated case of this kind:—"Incapable of lying down, the patient is seen for weeks, and even for months together, either reclining in the semi-erect position, supported by pillows, or sitting with the trunk bent forwards, and the elbows or forearms resting on the drawn-up knees."

"With eyes widely expanded and starting, eyebrows raised, nostrils dilated, a ghastly and haggard countenance, and the head thrown back at every inspiration, he casts round a hurried, distracted look of horror, of anguish, and of supplication; now imploring in plaintive moans, or quick, broken accents, and half-stifled voice, the assistance already often lavished in vain; and now, in an agony of despair, drooping his head on his chest, and muttering a fervent invocation for death to put a period to his sufferings."

Palpitation.

Among the general signs of cardiac disease some may be said to be direct, others

indirect: the former have obviously more value than the latter. Among the direct symptoms palpitation is one of the most common; the character of the pulse being also occasionally diagnostic may be included under this head: under it, also, turgescence of the jugular veins, pulsation in those veins, and *fremissement cataire*, may be included: the latter have, however, already been considered. The indirect—or, as they are more correctly termed, the secondary symptoms—are common to diseases of the lungs as well as of the heart. Under this head will be included congestion of the lungs, cough, dyspnoea, orthopnoea, hæmoptysis, pulmonary apoplexy, congestion of the liver, spleen, kidneys, and brain, anasarca, and effusion into the cavities of the pleura and peritoneum.

Among the direct signs of cardiac disease palpitation is perhaps the most constant and most frequent: it is often the first symptom which attracts the patient's attention, and it frequently distresses and harasses him throughout every stage of the disease, or until its final close. On the other hand, palpitation is frequently a prominent and troublesome symptom when the heart is in a perfectly healthy state.

It has already been said that, in the healthy subject, where the chest is well formed, and the heart and lungs have their normal proportions, the impulse of the apex of the heart is so slight that the individual is not sensible of it himself: the motion, in fact, is performed without his consciousness, and is only perceived in a very limited space when the hand is laid upon the parietes of the chest. Whenever, consequently, a person becomes sensible of the beating of his own heart, it may be said to constitute palpitation. Palpitation may therefore be defined:—An unusual action of the heart, perceptible to the individual, and inconvenient to him (though the latter is not essential), the impulse being usually stronger than natural, and the action of the organ often more rapid than in health, and occasionally intermittent or irregular.

Palpitation presents numerous varieties: sometimes it is so slight that the patient is unconscious of it, or makes no complaint unless questioned; at other times it is so violent as to elevate the clothes, and shake the bed upon which the patient lies. Sometimes the impulse communicated is a slight, rapid shock; sometimes it is strong, prolonged, and heaving, elevating the head of the observer; at other times the impulse is not altered, or is even weaker than natural. Sometimes the sounds of the heart are increased in intensity; and, in rare cases, so much, that the patient can hear them himself when he lies upon the left side; at others, the sounds are not at all increased

in intensity. In some cases palpitation sets in suddenly; in others, it makes its approaches very gradually. Sometimes the fits are short, quickly subside, and the patient is perfectly free from it in the intervals; at others, the fits are longer and more severe, or more or less palpitation is constantly present. Sometimes the palpitation is accompanied by uneasiness, by a sense of constriction, or of weight, or pain in the region of the heart, or by a sense of sinking or of fluttering in the epigastrium; sometimes by dyspnoea or orthopnoea; sometimes by headache, vertigo, or noises in the head: at others, nothing of the kind is observed, and palpitation is the only symptom we are called upon to treat.

Palpitation, although one of the commonest symptoms of morbid states of the investing or lining membrane of the heart, of its valves, orifices, or muscular tissue, frequently occurs independent of any organic change in this organ, and is not unfrequently a greater source of anxiety or alarm to the patient under such circumstances than in cases of organic disease. Thus it is a symptom in plethora, and in the very opposite condition—*anæmia*: it is a common attendant upon dyspepsia and derangement of the digestive organs, and it arises in debility from any cause: it is a frequent symptom in hysteria and hypochondriasis: it is not unusual in the early stages of pregnancy, and it accompanies several diseased states of the pulmonary organs.

The value of palpitation as a symptom mainly depends upon whether it is *symptomatic* of diseased states of the heart, or whether it is *sympathetic* of some other affection: hence it is of considerable importance that its cause should be determined. We shall therefore consider it here under two heads—viz., as it has its cause in organic disease of the central organ of the circulation, or as it occurs *independent* of cardiac disease.

Palpitation depending upon organic disease of the heart.—Palpitation depending upon organic disease of the heart usually, unless in cases of acute inflammation of the investing or lining membrane of the organ, comes on slowly and insidiously, and increases gradually: it is constant, although more distressing at one period than another: it is very generally combined with derangement of the general circulation, or with disorder of the respiration; and it is very generally also accompanied by well-marked physical signs, or by other general symptoms of cardiac disease. Palpitation will therefore be a symptom in pericarditis and endocarditis, in hypertrophy, and in dilatation of the ventricles, or when these two states are combined; in

diseased conditions of the valves or orifices of the left side of the heart, causing obstruction, or permitting regurgitation; in adhesion of the pericardium, the result of pericarditis; and in softening of the heart.

Thus, in acute pericarditis, or endocarditis, palpitation is often one of the first symptoms which attracts the attention of the patient or practitioner; the heart's action is more rapid than natural, and the impulse is increased. Cases, however, occasionally occur where the palpitation is so slight as scarcely to attract attention. In adhesion of the pericardium the result of pericarditis, more or less palpitation is generally likewise constantly present.

Again, palpitation is one of the commonest symptoms of hypertrophy of the ventricles: here the impulse is increased, often considerably, but the action of the heart is not more rapid than in health. In dilatation of the ventricles the palpitation is accompanied by increased loudness of the heart's sounds, but the impulse has not much real strength. In the combination of these two states, or hypertrophy with dilatation of the ventricles, particularly when the disease is advanced, the palpitation is often very distressing, and the paroxysms are frequently prolonged and severe.

In organic disease of the valves or orifices of the left side of the heart palpitation is very generally and constantly present; but, as they are usually accompanied by hypertrophy, with or without dilatation of the ventricles, and as they always tend to produce these morbid states, the palpitation has its cause partly in this complication. Finally, in softening of the muscular tissue of the heart, palpitation is frequent: here, however, it is of the passive kind; the impulse is feeble, and the heart's action usually intermittent and irregular.

Palpitation independent of organic disease of the heart.—Palpitation independent of organic disease of the heart is more common in the female than the male: it usually sets in suddenly, and is almost always intermittent. The impulse is often sharp and knocking, but never heaving or prolonged, and the action of the heart is generally rapid. The palpitation comes on in paroxysms, often when the individual is in a state of repose: it is readily excited by mental emotion; and the physical and general signs of valvular or other disease of the heart are absent.

The palpitation which occurs under these circumstances presents several varieties, and may be traced to several causes, some of which are intrinsic to the heart, others are extrinsic to it. Thus palpitation will ensue when the blood is returned to

the heart more rapidly than in ordinary, or when the motions of the heart are impeded, whether the exciting cause be seated in the lungs, in the parietes of the chest, or in the abdomen. Palpitation occurs in states of debility, whether this depends upon excessive evacuations, or arises in convalescence from acute disease; as well as in certain states of the nervous system, whether this be constitutional or acquired. Finally, it may ensue when two or more of the foregoing conditions are combined.

Thus, 1st. In a healthy subject, violent exercise on the one hand, or the indulgence in intoxicating liquors on the other, will hurry the circulation, and give rise to palpitation. But, in such cases, as soon as the exciting cause is removed, the effect ceases. In states of plethora, likewise, where blood is rapidly formed, and the vascular system becomes overloaded or oppressed, more or less palpitation is generally present.

2ndly. In cases where the bony parietes of the thorax are contracted and deformed; or in adults whose chests are narrow and extremities long; or in young persons about puberty, whose growth has been rapid, palpitation is often complained of. Here its cause appears to lie in the narrowness of the chest, which interferes with the free play of the heart, or with the free expansion of the lungs. Palpitation is also occasionally complained of in the advanced stage of pregnancy, in cases of large ovarian or other abdominal tumors, or in ascites, in which the descent of the diaphragm is interfered with, or pressure is exercised upon the large vessels.

3rdly. Palpitation is a very frequent symptom in states of debility, as in anæmia, whether this arises from profuse hæmorrhage or accompanies amenorrhœa; or where profuse evacuations of any kind have occurred; under this head sexual excesses and menstruation may be included. Palpitation likewise is a symptom of mercurial erithismus; and it not unfrequently arises during convalescence from acute diseases, particularly where mercury had been freely given, and after protracted fever it is by no means rare.

4thly. In persons of what is called the nervous temperament, palpitation is common, and is readily excited by mental emotion, or by trifling causes. In hysteria, particularly in that form which gets the name of spinal irritation, it is an ordinary symptom; and in cases of hypochondriasis it is by no means unfrequent.

5thly. Palpitation is not unfrequently induced by excessive study, by late hours, by the habitual use of strong tea, or the inordinate use of tobacco in the form of smoking; by the suppression of some

habitual discharge; by prolonged mental excitement, whether of an exciting or depressing nature; or by a sudden shock or fright. In these cases it partly depends upon derangement of the digestive organs, and partly upon debility or constitutional or induced irritability.

Lastly, palpitation is a common accompaniment of various forms of dyspepsia: here it is partly due to flatulence, which, by resisting the descent of the diaphragm, impedes the free expansion of the lungs, and interferes with the motions of the heart; partly to the reflex sympathy between the parts concerned. Under this head the palpitation which sometimes occurs in persons of a gouty habit, and which

is occasionally so distressing, may probably be included.

It not unfrequently happens in practice, however, that organic disease of the heart is associated with derangement of the digestive organs; with an anæmic state of the system; with a nervous and irritable habit; or with some of the other causes capable of giving rise to palpitation; by which the difficulty of the diagnosis will be considerably increased.

In the following table the more prominent characters of the palpitation, which depends upon organic disease of the heart, are contrasted with those of palpitation arising independent of disease of this organ:—

Palpitation depending upon Organic Disease of the Heart.

1. More common in the male than the female.
2. Palpitation usually comes on slowly and gradually.
3. Palpitation constant, though more marked at one period than at another.
4. Impulse usually stronger than natural; sometimes remarkably increased, heaving, and prolonged; at others irregular and unequal.
5. Percussion elicits a dull sound over an increased surface, and the degree of dullness is greater than natural.
6. Palpitation often accompanied by the auscultatory signs of diseased valves.

7. Action of the heart regular, irregular, or intermittent; not necessarily quickened.

8. Palpitation often not much complained of by the patient; occasionally attended by severe pain, extending to the left shoulder and arm.

9. Lips and cheeks often livid; countenance congested; anasarca of lower extremities common.

10. Palpitation increased by exercise, by stimulants and tonics, &c.; relieved by rest, and frequently, also, by local or general bleeding, and an antiphlogistic regimen.

Palpitation independent of Organic Disease of the Heart.

1. More common in the female than the male.

2. Palpitation usually sets in suddenly.

3. Palpitation not constant, having perfect intermissions.

4. Impulse neither heaving or prolonged; often abrupt, knocking, and circumscribed, and accompanied by a fluttering sensation in the præcordial region or epigastrium.

5. The extent of surface in the region of the heart, which yields naturally a dull sound on percussion, is not increased.

6. Auscultatory signs of diseased valves absent; bruit de soufflet often present in the large arteries, and a continuous murmur in the veins.

7. Rhythm of heart usually regular; sometimes intermittent; its action generally more rapid than natural.

8. Palpitation often much complained of by the patient; more readily induced by mental emotion, and frequently accompanied by pain in the left side.

9. Lips and cheeks never livid; countenance often chlorotic; anasarca absent, except in extreme cases.

10. Palpitation increased by sedentary occupations; by local and general bleeding, &c.; relieved by moderate exercise, and by stimulants or tonics, particularly the preparations of iron.

Immediate Cause of Palpitation.

The blood which circulates through the cavities of the heart is considered to be the natural stimulus to the contractions of the organ: thus, in a state of health, when this fluid is returned to the right side of the heart more quickly than in ordinary, its action becomes more rapid. In this way exercise increases the frequency of the heart's contractions, and hurries the circulation, which returns to its normal fre-

quency after the patient has remained at rest for a time.

In states of plethora, in which blood is rapidly formed, palpitation we have seen to be a frequent symptom; there is here an increased amount of blood in the vessels, and this fluid is of a more stimulant nature, perhaps; the palpitation which ensues in these cases is not accompanied by quickened action of the heart. In the very opposite condition to this—viz., anæmia—where the blood is poor and watery, and

deficient frequently in quantity, palpitation is also extremely frequent, and the heart's action is more rapid than in health: here the heart appears to contract more frequently, to compensate for the deficiency in the quality of the blood.

Again, when the valves or orifices of the heart are diseased, and the passage of the blood out of or through its chambers is impeded, palpitation ensues; the organ here is excited to increased action in order to overcome the obstacle to the transmission of the blood. Increased action leads eventually to increased nutrition; the parietes of the ventricles become hypertrophied under such circumstances, and the palpitation more marked.

When the parietes of the ventricles are thinned, or when the muscular tissue of the heart is softened, the contractile power of the ventricles is diminished; they are too feeble to propel the blood contained in their cavities, which become distended or overloaded: here the palpitation is of the passive kind; for although it is often distressing to the patient, the impulse of the organ is frequently too feeble to be felt, and its rhythm is often intermittent or irregular.

In all these cases the explanation of the occurrence of palpitation appears to be easy: this phenomenon is, however, frequently witnessed independent of any of the foregoing circumstances, as in mental emotion of various kinds: here the nervous system is generally considered to be the exciting agent, though the exact *modus operandi* is not quite clear.

Influence of the Coronary Circulation.

In considering the immediate cause of palpitation, writers do not appear to me to have taken sufficiently into account the coronary circulation, although there can be no doubt that it performs an important part, and that derangement of its circulation will be followed by derangement of the functions of the heart equally as when the circulation through the chambers of the organ is impeded or deranged.

The integrity of a muscle, and its healthy action, depend mainly, we know, upon its receiving a due supply of arterial blood: if this is sufficient, and of a good quality, the functions of the muscle will be performed with vigour; while, if the supply is too small, or if its quality is deteriorated, the functions of the muscle will be impaired. Now, the heart being a muscular viscus, requires, for the vigorous performance of its functions, an efficient supply of arterial blood: hence, although the blood which circulates through the chambers of the heart is the ordinary stimulus to the contractions of the organ, if the coronary arteries which convey the materials for its

nutrition carry it in insufficient quantity, or of a deteriorated quality; or if, on the other hand, it is conveyed in increased quantity, or is of too stimulating a quality, the functions of the organ will suffer.

Thus, in *anæmia*, the quality of the blood being deteriorated, and a given amount containing less of the materials of nutrition, it is necessary that a greater quantity should pass through the coronary vessels in a given period, and the action of the organ is accelerated in order to compensate for the deficiency. Again, in states of *plethora*, where blood is rapidly formed, the heart is excited to increased action, very probably in consequence of the stimulant nature of the blood which circulates in its vessels, and its increased amount.

Lastly, in cases of valvular or other disease of the heart, where considerable obstruction exists in the pulmonary circulation, and the venous blood does not undergo the necessary changes in the lungs, the coronary arteries will convey a mixture of venous and arterial blood to the tissue of the heart; the functions of the muscle become impaired, its irritability diminishes, and it is no longer obedient to the stimulus of the blood which distends its cavities: hence its action becomes irregular and unequal;—indeed, in the advanced stage of valvular or other disease of the heart where the pulmonary circulation is greatly impeded, the cessation of the heart's action, and the death of the individual, is probably owing immediately, in many cases, to the coronary arteries conveying venous blood to the tissue of the heart.

Before dismissing the subject of palpitation, I may observe that this symptom frequently is present in a marked degree in the class of patients who present themselves at hospital, without their appearing to be conscious of it. When questioned, they allow that they feel some oppression in the præcordial region, but hardly admit that it amounts to palpitation, though, when we come to examine the chest, the action of the heart is often much increased, and its impulse sometimes so strong as to raise the head of the observer. This, no doubt, arises in some measure from the sensibility being blunted by the ill oxygenation of the blood, and in some measure, also, from the parts having had time to accommodate themselves to their altered condition. On the other hand, it is no less remarkable how often, when palpitation depends simply upon functional derangement, the patient's attention is directed mainly to it; he is most unhappy in consequence, and can scarcely be made to believe that he is not the subject of organic, and therefore, in his opinion, of incurable, disease of the heart.

Original Communications.

REMARKS ON THE
VITAL STATISTICS OF THE
BOROUGH OF PLYMOUTH,
FOR THE YEAR ENDED ON THE 30TH OF
JUNE, 1850.

BY DR. W. HAMILTON.

[Continued from p. 536.]

THE births in the summer of 1848-9 and 1849-50 were 349 and 354, being an increase of 5 in the latter. In the autumn quarter this increase was still greater—from 391 to 411, or 20, giving a nett increase for the half year of 25. In the winter quarters, however, the numbers were 449 in 1848-9, and 409 in 1849-50, indicating a balance of 40, or 60 per cent., beyond the previous increase, against the first quarter, of the last half year of 1849-50.

On carrying our comparison to the spring, or last quarter of each year, we find the births in 1848-9 to have been 455, and in 1849-50 only 397, showing a farther reduction of 58, or 18 beyond the last, being a farther reduction of 40 per cent. The total falling off of the births in the half year, in which not a trace of cholera could be detected, of 98, is two more than the former computation gave,—a difference trifling in itself, but readily accounted for by the excessive number 8 which was rejected for two births upon that occasion, while 6 only would have been nearer the truth.

Upon a comparison, indeed, of the aggregate births of the two years, we find the balance against that just ended to amount only to 73, a circumstance fully accounted for by the actual increase of 25 during the first half. But this in no manner affects our inquiry, the object of which was to determine the probable number of women who were carried off between the third and ninth months of their gestation, whom we may now fairly assume to have numbered at least 98, or 0·95 per cent. of the whole number living at the commencement of cholera, between the marriageable ages of 18 and 50.

That this is no visionary opinion, which rests only upon the unsubstantial

basis of theoretical calculation, appears to be corroborated by a fact communicated to me upon what I regard as unquestionable authority, of parturition having actually taken place while the mother was labouring under the double affliction of cholera, and this in more than one instance, although I have been unable to ascertain the precise number.

But although these cases corroborate Dr. Shapter's statement with respect to Exeter,—that cholera did not in every instance prove fatal during pregnancy—they at least justify the opinion that the deficiency of 98 births on a comparison of the six last months of the two last years with each other, arose in great part, if not entirely, from an equal number of mothers having sunk under the violence of the pestilence before nature had succeeded in relieving them from their burden,—a number equal to above 58 per cent. of the entire number that died.

Dr. Snow, of Frith Street, Soho, in a valuable pamphlet on cholera, published last year by Mr. Churchill, of Princes Street, Soho, ascribes cholera to a local affection of the alimentary canal, arising from a poison introduced into it through the medium of water contaminated by percolation from sewers and cesspools. But such contamination has existed, more or less, for a period beyond human remembrance without producing any disorder analogous to cholera, in the character of an epidemic, of sufficient importance to attract the attention of the world, and sweep with the besom of destruction so vast and so fair a portion of our globe.

Although Dr. Snow's opinion is the result no doubt of attentive and extensive observation, and although the introduction of such a deadly poison was powerfully calculated to aggravate, if not create the disease, yet there is something in the peculiar features of the cholera, and, in the absence of all medical record of its existence in this country previous to 1832, when its course to our shores was marked in unmistakeable characters across the vast continents of Asia and of Europe, we may perhaps be justified in referring it to some obscure and yet undiscovered origin. The unwholesome water may have created the predisposition, but the latent cause was wanting to call the slumbering malady into mischievous and active existence.

The same objection and the same reasoning also appear to another cause which he assigns for its production,—namely, the want of personal cleanliness; but powerful as this exciting cause is in the production of typhus, and the other common forms of epidemic, the proximate cause of cholera, in its Asiatic or malignant form, was yet wanting to call into being that hitherto unknown malady. The deadly weapon of mortality might have been loaded to its very muzzle, but the percussion cap of cholera was yet wanting to produce the explosion, and propel the morbid poison on its pestilential mission. Similar objections apply with equal force to all the other causes assigned for this destructive and mysterious malady, whose latent origin has yet been veiled from human eyes.

That want of personal cleanliness prepares for its reception, and aids its dissemination after the specific poison has been called into actual existence, as well as augments its virulence, is abundantly proved by Dr. Snow, who quotes, in confirmation of his own experience, that of Dr. Lichenstädt, who informs us, in a work which he published on cholera in 1831, and of which notice is contained in the 37th vol. of the Edinburgh Medical and Surgical Journal, that—

“At Berditscher, in Volhynia, a place of a few thousand inhabitants, no less than 900 were attended in 31 days. Among 764 of these were 658 Jews”—above 86 per cent.—“and only 106 Christians,”—or somewhat under 14 per cent.—“although the Jewish population is far from being proportionally so great; and among the Christians attacked the deaths were 61·8 per cent., while among the Jews they were 90·7 per cent. The only reason assigned by the reporter for these extraordinary differences is the excessive disregard of clean linen among the Jewish inhabitants.” And to this extract from Dr. Lichenstädt Dr. Snow adds, that—

“The first appearance of cholera in many towns of this country in 1832 was in courts and alleys to which vagrants resort for a night's lodging, where it often lingered for some time before spreading to the more cleanly part of the people,” p. 10.

With the Jews of Plymouth, however, from the superior comforts they enjoy, and the superior attention they pay to

domestic and personal cleanliness, the reverse was the case; and in the recent attack they enjoyed an exemption to a remarkable extent, only two of their number having been attacked, neither of whom died. Neither did cholera make its first appearance among us in those localities in which, both for their accumulated filth, and the character of their inhabitants, it might have been expected, had it originated from the ordinary causes of epidemics. In 1832 it made its first appearance at Coxside, in the vicinity of Sutton Pool; and in 1849 in Union Street, both undoubtedly low situations, hardly elevated above the ordinary high water mark, but neither, the latter more especially, admitting of a shadow of comparison with any of those localities in which it afterwards raged with the greatest fury. What makes this circumstance perhaps more remarkable is, the fact recorded in the Registrar's Annual Statistics for 1849, in which, in a note upon the 22 deaths from cholera, 12 of which took place in the June quarter, we are told that—

“The cholera cases reported in the three first quarters are either infantile or English cholera. Of the 12 cases that occurred in the last (June) quarter 9 occurred in the Sound, among the passengers and crew of the ‘American Eagle,’ emigration ship; the remaining 3 were those of an Irish emigrant in Stonehouse Lane, the man from Noss, and another in Leaze Street.”

And in the Quarterly Report of the Births, Deaths, and Movement of the Population for the June quarter of 1849, which appeared in the Plymouth Journal, it is remarked that—

“The health of the town has been steadily and progressively improving, and the mortality proportionably decreasing throughout the quarter, notwithstanding the destructive ravages of cholera in other parts of the country, and even in our immediate vicinity. On the 18th of April 8 cases, 2 of which terminated fatally from neglect of the premonitory symptoms, occurred in a narrow and filthy locality, close to the waterside in Stonehouse, known by the name of Water Lane; but the disease did not spread farther, notwithstanding the peculiar fitness of the locality for festering and diffusing contagion.

“An emigrant ship, bound to the United States, put in here for medical

assistance, in consequence of cholera having appeared among her passengers; but, notwithstanding the temporary alarm produced by her arrival, and the subsequent occurrence of a few deaths on board, the prompt assistance given, and the active measures adopted by the public and municipal authorities, soon arrested the progress of the destroyer, and the vessel has proceeded on her voyage with a clean bill, and without leaving us any evil recollection of her visit.

"Two deaths, we understand, occurred from cholera; one in our hospital, near Princes Square, the other in Stonehouse Lane; but, in both cases, the victims were strangers to the town,—the one a man from Noss, who brought the malady with him from that miserable and filthy village, and the other an emigrant, who arrived while labouring under the malady. In both these cases, from neglect of the premonitory symptoms, medical aid came too late, and man could only look on and lament his want of power to avert the catastrophe. In none of these cases, however, did the mischief extend beyond the immediate victims themselves, as might have been expected, had cholera partaken of the character of variola, rubæola, and other disorders which experience teaches us to regard as contagious."

Thus, not only had we the complaint raging within our waters in the dense community of an emigrant ship, from which some of the victims were brought on shore to undergo the hazardous investigations of an inquest, and lay their remains within our soil, but even a spark fell amidst the accumulated combustibles of Stonehouse Lane without producing a conflagration. But when the flame burst out it was not in the spot where the spark had fallen, and where the materials for combustion were ready for ignition; but in a different and far less insalubrious locality, where no materials were prepared for its reception, and where its appearance was least of all to be apprehended.

Again, the case of H.M.S. Apollo, in which cholera broke out without an apparent cause after she had been a week at sea, as reported in a letter from Mr. Charles Kidd, of the 26th July last, inserted in the *Medical Times* of the 3d of August, spreads a darker veil of mystery over the origin of cholera than ever; and seems to show that most, if

not all, of the causes to which we have been accustomed to ascribe it, have obtained their reputation from a fortuitous coincidence, rather than any real connection,—as will appear when we come to inquire into the atmospheric phenomena to which some visionary imaginations have referred it.

Mr. Kidd, in his letter, acquainted us that he saw the 59th regiment, embarked in the Apollo, "leave Ireland without a man sick,—the men, in fact, picked out for their general health,—and proceed to sea. When a week from shore they were attacked by cholera in its worst possible form, the disease, from the 18th of June to the end of that month [when, I believe, they were only off Teneriffe], and all through July, up to the 11th of August, when they sighted the coast of South America, wearing one frightful shape, and cutting down the men with little distinction. Out of 512 men, no fewer than 320 were on the sick list; and Dr. Frazer, who kindly furnished us with the particulars, seems to have known true Asiatic cholera, from long acquaintance with it in the East. The vessel arriving off Rio Janeiro, you will recollect, and the cholera still cutting down the troops, who crowded about the decks cheerless and spiritless, their eyes sunken in their sockets, and their faces pale and ghastly. They were disembarked on an island, lent for the purpose by the government of Brazil, when the cholera, as if by magic, at once disappeared. My impression at the time, from this single fact," continues Mr. Kidd, "was that it was true Asiatic cholera, from causes merely sporadic." Amid such a diversity of opinions, and such a multiplicity of conflicting facts, it would ill become me to offer a dogmatic opinion. But, in the hope of throwing some glimmering of light on a subject so enveloped in darkness, I have been led to place in juxtaposition such opinions and facts as were within my immediate reach, leaving the conclusions to those more competent to form them.

Cholera, having once effected a firm lodgment in the town, committed, as might have been anticipated, the greatest ravages in those localities in which the soil was best adapted to foster and retain it; where the filthy, dissolute, and intemperate habits of the inhabitants, their extreme poverty and wretchedness, the density with which they were

crowded together in a small and unwholesome space, joined to the most defective sewerage and ventilation, singularly predisposed, them for the reception and propagation of disease. What these particular localities more especially were it would be superfluous now to point out, since they are sufficiently known to the medical and municipal authorities, upon whom the responsibility devolves of guarding against future invasion.

With the exception of these localities, however, in which filth, poverty, and vice severally contended for ascendancy, I cannot find that cholera was influenced by any particular temptations in its choice of the localities from which its victims were culled.

Selecting from the statistical tables of the registrars twelve of the most salubrious localities in each of the two registration districts, corresponding as closely as possible in the amount of their mortality, their elevation above the sea, and other circumstances, in order to ascertain the effect of altitude, dryness, ventilation, &c. upon their respective mortality, I found that the 19 selected in St. Andrews gave me 74 deaths in 72 days; the 12 in Charles, 46 deaths in 38 days, marking a somewhat greater amount of intensity in the latter.

To present in a more intelligible form the amount of concentration or diffusion in each of these, I shall enumerate the localities, assigning to each its proportion of mortality and the date of its occurrence, commencing with those in which it was greatest in each of the two divisions; after which I shall exhibit them, with their corresponding elevations above the mean level of the sea, in a tabular form.

And first, in St. Andrews, Morley Place and Lanes head the list with 11 deaths on 10 days—namely, on the 15th and 17th of July, and the 15th, 19th, and 30th of August, a single death on each of these days; 2 deaths on the 12th of September; a single death on the 16th, 21st, and 25th of that month, and on the 18th of October. Cambridge Street and Lanes follow next, with 10 deaths in 9 days—namely, 1 each on the 18th of July, and on the 12th, 22d, 28th, and 29th of August; 2 on the 8th of September, and 1 each on the 11th and 13th of October and 3d of November. Claremont Street, 9 deaths in as many days—namely, on the 20th of July, 12th,

13th, 14th, and 17th of August, and 9th, 11th, 12th, and 17th of September. West Hoe and Sandy Cove, 9 deaths in 7 days—namely, 1 each on the 25th, 26th, and 31st, and 2 each on the 28th and 29th of July; and 1 each on the 18th and 19th of September. Frankfort Street, 8 deaths in as many days—namely, 12th and 15th of August, and 6th, 12th, 16th, 18th, 23d, and 28th of September. York Street and Lanes, 7 deaths in an equal number of days—namely, 19th and 23d July; 24th, 27th, and 29th of August; 6th of September, and 29th of October. William Street and Lanes, 5 deaths in as many days—namely, 16th of July; 11th, 15th, and 28th of August, and 25th of September. The west or St. Andrew side of Cobourg Street and Lane, 5 deaths in as many days—namely, 11th, 25th, 28th, 29th, and 30th of August. Eldad Place, 4 in as many days—namely, 22d, 23d, and 29th of July, and 11th of September. Grosvenor Place and Melbourne Street, 2 deaths; 1 on the 15th of July, and 1 on the 24th of August. George Place and Mulgrave Place the same, on the 24th and 31st of August; and Whimble Street the same, on the 22d of August and 24th of September.

In Charles district we have Gasking Street, occupying the declivity between Gascoyne Terrace and Higher Street, where cholera appeared in its most abrupt and concentrated form; and hence possibly deriving an amount of insalubrity from which its rapid descent might have been expected to exempt it, furnishing 10 deaths in the brief interval of 4 days, coinciding closely with the mortality in Higher Street—namely, 4 on the 16th, 3 on the 18th, 1 on the 19th, and 2 on the 24th of September. Ebrington Street and Place, and Garden Street, 8 deaths in 6 days—namely, on the 16th, 17th, and 18th of September 1 each, on the 19th 2, on the 21st 1, and on the 29th 2. John Street and Lane, 6 deaths in as many days—namely, the 28th and 31st of August, and the 2d, 7th, 10th, and 11th of September. Green Street 5 in 5 days—namely, 5th, 18th, 22d, and 26th of August, and 22d of September. Treville Street 4 in 4 days—namely, the 16th of July, and the 4th, 7th, and 11th of October. Gibbon Street 3 in 3 days—namely, 3d of August, and 8th and 10th of October. Gilwell Street the same—namely, the 7th and 18th of August, and 27th of September. Clarence

Street 1 on the 2d of September. East side of Cobourg Street 2 in 2 days—namely, 22d and 23d of September. Buckwell Street the same—12th of August and 26th of September. Borough prison, nearly on the highest and most airy part of the town, isolated from other

buildings, and but newly completed, 1 death on the 8th of August; and Saltash Street 1 on the 18th of July. In the following table the altitudes are taken from the mean level of the sea, and were roughly deduced from observations made with the aneroid barometer.

Table of Mortality—Intensity of the under-mentioned Places.

Hence it appears that in an equal number of places corresponding as nearly as possible in elevation and other particulars, the mortality was nearly equal, being at the daily rate of 1·06 in St. Andrews, and 1·2 in Charles.

When I resided in Oxford Street in 1892, one of the most airy and driest streets of the town, running from east to west along the ridge of the acclivity up which Cambridge and York Streets ascend, at an elevation of more than ninety feet above the mean level of the Sound, two deaths from cholera took place in that street, neither of the victims of which belonged to those classes whose confined dwellings and extreme poverty rendered them peculiarly obnoxious to attack. On the contrary, they were both ladies moving in the higher classes of society, living in well-ventilated houses, and surrounded by all the abundances, comforts, and conveniences of genteel society. Of these deaths, one took place in the house adjoining my own, both of which, standing on the north side of the street, and fronting down Cambridge Street, en-

joyed, without the possibility of interruption, the fullest play of the sea breeze from the south as it swept over the Hoe from the waters of the Sound. The circumstances attending the death of this lady are sufficiently remarkable to deserve notice here.

Mrs. Fortescue, the lady in question, was, as I should judge from her appearance, between forty and fifty years of age, in good health, and had two sons; the eldest I should imagine about four-and-twenty, and in holy orders. This lady, about the time that cholera was at its height, took a walk out one evening with some friends, and returning home through Bilbury Street passed the funeral of a poor person whose coffin was conveying on a bier to the burying-ground of Charles, having recently fallen a victim to the prevailing pestilence. On passing at the distance of some feet from the funeral procession, when nearly abreast of the coffin, Mrs. Fortescue exclaimed with a shudder, "Faugh! what a horrible stench." This observation attracted but little notice at the time, since the stench of which she complained was

unperceived by any other of the party; and the circumstance would have soon been forgotten but for the results which followed.

Soon after her return to her own house, Mrs. Fortescue, who had no recollection of any other exposure to the unknown causes of the malady, and who up to that moment had conceived herself to be in the enjoyment of the most perfect health, and had no mental apprehension which might have predisposed her to the reception of the complaint, became conscious of the presence of unusual symptoms for which she was unable to account. These rapidly increased, until, in a very brief space of time, cholera stood fully revealed in all the unmistakable horrors of its most malignant form; and before the dawn of another day arrived, she was herself added to the number of helpless victims who had fallen beneath the axe of the destroyer.

After the performance of the last offices of piety to the sad remains of their surviving parent, her sons gave up the house which had witnessed their loss, and removed from Plymouth, since which time I have not seen or learned anything about them.

Here, then, was a case of cholera immediately succeeding exposure to a narrow stream of pestilential gas escaping from some unclosed openings in the coffin containing a body in a state, no doubt, of rapid decomposition, and not to be traced to any other of the causes to which it has been commonly assigned, and occurring in a locality the least favourable to the production of what are regarded as diseases of contagion, but singularly in accordance with a statement contained in the Medical Times of the 3rd of August, 1850, which shows that cholera is little affected by climate or elevation, and passes without difficulty those limits which the worst forms of typhus have never yet been known to transgress. The statement is as follows, at p. 126:—

“According to letters received from the Andes, it would appear that cholera was prevalent at Bogotá, an elevation of 7,800 feet; this is higher by 6,000 feet than the point beyond which yellow fever has never passed in these countries.”

Hence it is clear that the proximate cause of that peculiar form of mortality, of which the only authentic account

dates back less than three-quarters of a century, and which has been so fatally known among ourselves by the name of the Asiatic or malignant cholera, is yet to be sought for among those capricious mysteries of nature which Heaven has, no doubt wisely, been pleased to place as yet beyond the grasp of human penetration.

But whatever that latent cause may be, not a doubt can be entertained that imperfect sewerage, filth, and defective ventilation, constitute the soil in which the malady most readily takes root and flourishes in the greatest luxuriance; and that consequently, as Dr. Snow, Dr. Shapter, and Dr. Roe very justly observe, attention to these is the only probable method of averting the danger or diminishing the mortality. Of this, Exeter furnishes an instructive and valuable example; for, bearing its full share of the affliction of 1832, it escaped nearly scatheless in 1849, in consequence of the attention paid in the intermediate space of time by the proper authorities to the sanitary condition of the town, and fully corroborating the opinion expressed by Dr. Shapter at the 281st page of his valuable work, where, speaking upon the authority of his own personal experience in 1832, he says, that—

“I feel justified in asserting the Asiatic cholera to be an epidemic, rendered general and fatal by external circumstances; and that without these it is, comparatively speaking, a manageable, if not a preventible, disease.”

There can be little doubt that Exeter owes its comparative exemption from this scourge in 1849 to the removal of those external circumstances of which Dr. Shapter speaks: and had the municipal authorities of Plymouth used equal diligence, that town would have enjoyed, in all human probability, an equal amount of exemption, and not had to mourn the loss of 819 of her most valuable citizens in addition to the 779 swept off in 1832.

[To be continued.]

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 28th September, 1850:—

CASE OF
SLOUGHING OF A MALIGNANT
TUMOR WHICH CONTAINED THE
FEMORAL VESSELS:

CICATRIZATION OF THE WOUND—DEATH
FROM RETURN OF THE DISEASE.

By J. A. KINGDON.

(Read before the Abernethian Society, December 18th, 1849).

THE following case is of value as well for its surgical importance as its pathological interest:—

Evan Davies, æt. 47, policeman: a robust man, of florid complexion, who had always enjoyed good health, was admitted into Henry's Ward, October 5, 1849, under the care of Mr. Lawrence. He stated that he first perceived a swelling in his right thigh nine months previous to his admission, and that it appeared a fortnight after the receipt of a kick on the part: during the last ten weeks it had remained stationary, but had grown rapidly before that time. He has taken mercury, and been treated locally with leeches and blisters.

On examination it was found that the tumor was hard, unyielding to the touch, and deeply seated, though apparently (from its free lateral motion) unconnected with the bone; it was situated rather above the middle of the thigh, and rendered the integuments prominent close above the inner border of the sartorius muscle. The femoral vessels were supposed to lie either behind or to the inner side of the tumor, and to be unaffected, as the pulsation of the anterior tibial arteries was felt to be equal in both feet. He could walk five or six miles without inconvenience, but much exercise prevented sleep, by causing numbness of the leg, and some pain in the tumor. He complained likewise of a shooting pain at the inner side of the knee and ankle; and although the tumor was not universally tender, yet pain was produced by pressure towards the inner side. He was ordered to take Pil. Saponis Opio, c. gr. v., that night, and to apply a linseed-meal poultice to the tumor.

October 12.—The propriety of an operation was acknowledged by the other surgeons of the hospital in con-

sultation with Mr. Lawrence, although, from the position of the tumor, doubts were entertained regarding the facility of its removal. Pulse 84, regular; tongue clean; bowels open.

13th.—1½ P.M. (Saturday): the patient being fully under the influence of chloroform, Mr. Lawrence made an incision about eight inches in length over the tumor, in the long axis of the limb: the sartorius muscle was exposed and divided, and the more superficial part of the tumor loosened from its connections. In consequence of the deep attachments, a transverse incision became necessary, by which the saphena vein was divided, and immediately compressed above the knee. By these incisions the tumor was fairly exposed, and detached from the surrounding textures for some depth on either side: it presented a smooth, circumscribed outline, and was hard, though elastic to the feel; a slight incision made into its substance was followed by active arterial hæmorrhage. To loosen the mass from its deeper adhesions its distal margin was supported by the left hand of the operator, and an incision made close to its substance; this stroke of the knife was followed by a sudden and voluminous gush of florid blood, as from a wound of a large artery; the bleeding orifice was soon seized, and secured by ligature; yet much blood was lost. Owing to the deep and obscure attachments of the tumor, its extreme vascularity, and probable malignancy of character, it was deemed inexpedient to pursue the operation farther, as that step would have involved the necessity of tying the femoral vessels close above the morbid growth,—a course which, in the exhausted state of the patient, seemed to be very dangerous. He was removed to bed in a very low state; he vomited much, and complained of pain in the region of the knee, but not in the seat of the disease.

4½ P.M.—Still continues sick, but is free from pain; complains of chilliness, although he is perspiring freely; pulse 90, small and feeble. There has been no hæmorrhage since the operation: the edges of the wound were approximated by sutures, and water dressing applied. An effervescing saline draught was given.

14th.—Slept but little last night on account of sickness: the vomiting and nausea still continue: the wound looks

well, and he states himself to be free from pain.

15th.—Sickness again prevented his sleeping; he feels hungry, but can retain no food; there is no perceptible difference in the temperature of the feet; skin warm and soft; pulse 114, small and feeble; tongue pale and moist; bowels not open; there is slight redness around the wound, which is otherwise healthy; the stitches were removed. Ordered, of Scheele's Hydrocyanic Acid miss. to be taken in an effervescing draught three times daily.

16th.—Continued vomiting prevented sleep; but in other respects he remains in the same condition as yesterday; the redness of the wound has slightly increased, and suppuration has commenced feebly. Ordered a mustard poultice to the epigastrium, and a bread and water poultice to the wound; to continue the drops.

17th.—He was much relieved by the mustard poultice, and slept for five or six hours last night: he has had but little sickness this morning; the wound looks well, and is suppurating freely; the surface of the tumor, as well as the rest of the wound, is red and granulating.

18th.—Slept tolerably well last night, and is no longer sick: he has taken some bread and cheese and porter (for which he craved) with relish: pulse 112, soft; tongue thinly furred and moist; bowels not open.

20th.—The bowels were freely relieved after a dose of the ordinary house medicine; and in consequence he reports himself as feeling much better to-day. A pint of porter daily.

22nd.—He has not slept well for the last two nights: there is an erythematous blush on the upper and outer side of the thigh, and slight enlargement of the limb below the knee, with pain in the ankle; the wound looks well, and the secretion is copious and puriform; skin hot; pulse 120, small and weak; tongue pale and moist: he has no appetite, and is thirsty.

24th (twelfth day after operation).—Dozes occasionally, yet gets no sound sleep: he moans continually, but not from pain; the redness of the thigh has extended somewhat, and is rather more intense; the cut edges of the wound are looking well, and suppurate healthily; but there is a *black spot in the centre of*

the tumor, and the granulations around are pale and indolent.

29th.—The erythema has greatly subsided, and he is now able to sleep comfortably; the leg is less edematous, and quite free from pain; the wound suppurates freely; *the whole of the tumor* is converted into a black, ragged, and *sloughing mass*, embedded in, and partly overlapped by, the healthy granulating surface of the surrounding parts: it is without sensation.

30th.—He was ordered to take half a drachm of Battley's Liquor Cinchona Cordifoliae three times daily: a mutton chop daily.

November 2nd.—He eats his mutton chop with relish, and says that he feels better; he sleeps well, and is free from pain; the wound looks healthy; a bent probe passes down three inches on either side of the blackened mass; there is a small bed sore over the sacrum.

10th (twenty-eighth day after operation).—For the last week he has been gradually improving: pulse 100, still feeble; tongue clean and moist; bowels open; his appetite is good; the wound discharges healthily; the slough is separating.

At this day's visit Mr. Lawrence removed, without using violence, the mortified tumor, by elevating the mass with forceps, and separating the more firm attachments with the scissors. On minute inspection, the slough, the size of an ordinary orange, was found to be perforated by a very large artery; and more towards the centre of the mass another canal with less distinct coats lying parallel to it: these, from their size and relative position, were evidently the femoral vessels.*

12th.—The wound is filling rapidly; his appetite has increased.

21st.—The limb has been rolled from the foot to the groin for the last week, and is much diminished in size: cicatrization advances.

December 13th.—Walks about with the aid of a stick: the wound has nearly closed.

19th.—Discharged well.

On leaving the hospital, he went to his house in the north of Wales; and in a letter received from him a fortnight after his dismissal, he stated that he had

* The preparation is in the Museum attached to the Hospital.

borne the journey well, but that he had not left the house since his arrival, in consequence of return of pain in the thigh. Tidings of his death were brought to the hospital at the expiration of six weeks, accompanied with sections of the disease, which had reappeared in his thigh, and shewn itself in the lungs also. A post-mortem examination was made; but as the gentlemen who conducted it were not fully aware of the circumstances of the case, the chest and thigh only were examined. The lungs on both sides were studded with masses more or less considerable of a yellowish-grey substance, which presented the appearance of firm medullary cancer; the diseased mass which had returned in the thigh possessed the same characters as those found in the lungs. It is much to be regretted that neither the condition of the femoral artery, nor the extent or attachments of the tumor, were investigated.

Among the many points of interest presented by the foregoing history the following appear to be more especially worthy of notice:—

Diagnosis.—The subject of the disease was a man who had all the appearance of robust health; his face was ruddy, and free from that tawny-yellow tinge that so often accompanies a malignant diathesis. The tumor, situated rather above the middle of the thigh, did not cause much uneasiness, although lancinating pains were sometimes felt shooting towards the ankle. It was deeply seated, but moveable, hard, and not materially tender when touched: there was no distension of the veins of the skin over it, nor any enlargement of the limb below; the inguinal glands were unaffected.

These symptoms could scarcely be said to indicate a malign nature; the locality of the disease (the bone being unaffected) was not one in which such tumors generally occur, although perhaps the depth might have favoured the supposition; and the lancinating pains were thought to be occasioned by the pressure of the mass upon some branches of the anterior crural nerve. Most patients are apt to ascribe the commencement of their maladies to some special cause; but the value of their theories is often very questionable. In the present instance the origin was attributed to a blow, which (granting the patients to

be correct in their assertions) is certainly a very common cause for many local affections; yet there are many surgeons of eminence who consider it a matter of diagnostic importance, more especially in doubtful mammary tumors; for it is well known that in cancer of the breast the patients almost invariably attribute the commencement of the disease to some local violence, while in other affections of the organ such an origin is neither so frequently nor so positively stated.

Operation.—From the free lateral mobility of the tumor, and from its seemingly well-defined boundary, no great difficulty was anticipated in its removal, although the neighbourhood demanded caution. But when a free exposure of its anterior surfaces was made, and small nodules of disease were found stretching up towards the crural ring, and when the depth of its attachment was ascertained by dissection, then was the severity of the undertaking in some measure appreciated. The case was not even at that time thought to be desperate; and, although it was considered somewhat strange that the femoral vessels had not become apparent, still further was it from the mind of the operator to conceive that the pulseless mass which he was handling and dissecting out was permeated by them. When, however, at length this truth was discovered, there remained but one alternative,—to tie the iliac artery, and then extirpate the disease,—or leave the patient as he then was. The operation had lasted about the half of an hour, and the patient had lost a considerable quantity of blood; it was without much hesitation, therefore, that Mr. Lawrence stayed his hand.

Sloughing of tumor.—The prognosis of the man was decidedly adverse to the patient's well-doing; and certainly so happy a termination as the sloughing of the disease was not anticipated; for, under the ordinary circumstances of a cancerous growth, such a result is by no means frequent, although occasional instances are to be met with in the works of surgical writers. Abernethy* relates the case of a man, aged forty, who was affected with medullary sarcoma of the glands in the left groin; the integuments ulcerated over the tu-

* Classification of Tumors, p. 60.

tumor, and the mass was separated by sloughing; profuse hæmorrhage ensued, which was stopped by pressure; granulations sprang up, and the wound cicatrized. A similar occurrence happened soon after in the opposite groin, but before the cicatrization was complete the patient died exhausted. Travers* speaks of more than one case where cicatrization has been complete after the sloughing of cancerous tumors; and relates the case of a lady who remained well for several years after the occurrence.

Boyer† gives the case of a Russian princess, who, after having consulted most of the eminent surgeons of Europe for cancer of the breast, at last tried the mineral waters of Barèges as an external application. While under this treatment mortification ensued in the tumor, which was of a large size, and by this process it was entirely separated. The very extensive wound healed completely; but shortly after cancerous tubercles were developed in great number in the vicinity of the cicatrix, and the patient died at Paris eight months after the event, which had inspired her with the hope of a radical cure.

Bérard‡ mentions briefly the case of a woman, in which cicatrization of the ulcer took place after sloughing of the tumor, although the system was generally affected, and cancer occupied the internal organs. He relates another case also, where sloughing took place in a large cancerous tumor situated in the thigh of a woman; but that was speedily followed by death.

Richerand§ too, affords an example of cicatrization after the sloughing of a cancerous tumor:—A woman, aged 48, of strong constitution, was admitted into the Hospital of St. Louis with a cancerous breast. The very hard mass softened, a violent inflammation of the skin and cellular tissue covering the tumor was set up, mortification followed, and the whole mass was separated: cicatrization was complete in less than two months.

Sir Everard Home, and indeed most surgical writers who have treated of cancer, mention similar cases: but of all that have been related the foregoing are perhaps the most complete.

In the museum attached to this hospital there are two specimens of cancerous tumors which were separated by sloughing.* The one is the case of a woman 47 years of age, from whom a cancerous breast was removed by operation. The wound healed readily, and remained well for nearly three months; then, however, a tumor began to grow under the cicatrix, which rapidly increased, and was separated by sloughing at the end of three months. She died exhausted nine months after the operation. Hard white tumors of cancerous appearance were found in the lungs.

The other specimen is from a woman 40 years old, in the middle of whose back a large brain-like medullary tumor was situated. The integuments sloughed over it at the end of four months; and, as she was endeavouring to raise herself in bed, the whole mass fell out through the slough: it was followed by profuse hæmorrhage, and she shortly after died.

Now in all these examples the sloughing was spontaneous,—i. e., it occurred as a process of the disease, and was not induced by any medical interference; therefore he argued that their analogy to the case related above was not good. But it must at the same time be remembered that the tumor did not at first present signs of death; it was, on the contrary, covered with healthy granulations up to the twelfth day after the operation, and, as was afterwards discovered, contained within itself the very source of its existence.

The mortified mass was so thoroughly disorganized that, under the microscope, little else could be discovered than a crowd of molecules and granules, which had the peculiar appearance of oil-globules, and an occasional cluster of such shining particles held together by an enveloping membrane. Similar appearances have been figured by Professor Bennett, of Edinburgh,† and considered by him to be degenerated or disintegrated cancer cells, identical with "fatty degeneration," and an evidence of decay. Such, too, appears to be Paget's‡ interpretation of Rokitsky's "saponification of cancer." Now Rokitsky holds this to be one of the means whereby

a spontaneous cure of the disease may be effected; whereas most surgical writers on the subject look upon it as an unfavourable symptom, and one that is rapidly followed by the development of the disease in internal organs. Ledran,* Rouzet,† Richerand, and Boyer, entertain this view, and their opinions are furthered by the present case.

To discuss every point of interest in the case—the position of the tumor, the cause of the sloughing, the process by which rather more than an inch of the femoral artery was separated without hemorrhage, and the rest—would be no light undertaking, nor one in accordance with the object of this paper; so that upon the mere record of the facts must depend its value.

ON

PNEUMONIA IN THE TROPICS.

By E. H. A. HUNTER,
Staff-Surgeon.

[Continued from page 221.]

Pneumonia.—This, as we have already had frequent occasion to show, is a rare disease within the tropics, at all ordinary elevations, inasmuch that we can only remember two or three well-marked cases, and even these were associated with cardiac disease (hypertrophy with dilatation) in a high degree. Only one had reached the stage of "purulent infiltration" (See "India Journal of Medical Science," Calcutta, 1836-6). Pneumonia, however, and generally of a lower lobe, is occasionally met with as a complication of fever in the more northern provinces of India, during the cold or winter season; and in Scinde, but particularly in Afghanistan, in the form of pleuro-pneumonia, united with fevers of the remitting and intermitting types, it forms endemics (epidemics) of the most fatal tendency. On emerging from the Gundava Pass, from Beloochistan, in December 1839, and for two or three months afterwards, the 2nd, or Queen's Royal, and 17th Regiments, suffered much from a fever of this kind (See "Annual Report" of these regiments for 1839-40, in "the Bombay Transactions," No. iii.); and in a still higher degree, H. M. 40th Regiment, some years subsequently, at Kwettah,

immediately above the Bolan Pass. It is true both in that and the 17th Regiments the disease was returned simply as pneumonia, as it was also at first in the 2nd, or Queen's. By the returns the mortality in the 40th Regiment in 1841-2, was not less certainly than 50 or 60 per 1000 of strength, from this disease alone. In these fevers we found quinine the grand remedy, the almost "sine qua non," indeed; a moderate venesection in the first instance, and cathartic, but afterwards calomel, antimony, and opium, alternately (every second hour or so), with some saline febrifuge during the exacerbation, quinine in the remission or intermission; not waiting for either being very perfect, however, as there is no time to lose. We would now try it upon the present West India system, during the exacerbation also. Two cases of this fever in Scinde we saw terminate fatally in a few hours, with much of the coldness and blueness characteristic of malignant cholera ("febris algida"), and without the least effort at reaction. In both these, on admission, the left side on percussion sounded dead almost as a log, and on the post-mortem examination the lung was found to be nearly equally solid, and of immense size, apparently both lobes being involved. The greater number, however, presented a pleuritis and pneumonia more or less combined, the pleuritis latterly predominating; that is, as we approached the sea coast, Kuratchee; and this not only with the 2nd, or Queen's, but also with the 17th about a month after. (To explain: immediately after our arrival at Kuratchee with the 2nd, or Queen's, we were sent back to take medical charge of the 17th Regiment, and thus had an opportunity of seeing and watching the disease in both regiments to its close.) The excellent effects of quinine we saw verified in several cases on the "per contra principle:" but of these we shall here only particularize three. Two, treated as pneumonia by copious bleeding, &c., were transferred, as was supposed in a hopeless state, with black parched tongues, diarrhoea, and extreme prostration. No quinine had been exhibited: nevertheless, within ten days, both were embarked on the Indus, convalescent, and fully recovered. Small doses of Hyd. c. Creta, and Dover's powder, alternately with quinine, were exhibited as medicine. Sago and wine

* Tr. des Opér. de Chir.

† Rech. sur le Cancer.

for diet. The third was just the opposite of these. The patient had been admitted in the usual way, with the fever, pain in the side, &c., but next morning was so perfectly apyrexia and well, apparently, that quinine was not administered, under the impression that the results latterly might be due rather to some favourable change in the nature of the disease itself. At 11 A.M. the fever and pulmonary symptoms returned, and at 5 P.M. he was moribund.

Pneumonia in Afghanistan occurs also in an uncomplicated form in the winter season, but not very often comparatively; owing, perhaps, to the dryness of the climate. At all events, we had only three cases with the 2d, or Queen's, during October and November, notwithstanding in these two months we marched nearly 500 miles, the greater part over untrodden mountain passes, under a burning sun by day, but with the thermometer often at 14° in the tents by night. Coming along to the east of the Suliman range,—indeed, from the Great Salt Water Lake to the source of "the Larah,"—that is, from about lat. 32° 20, to 30° 30, and eight or nine thousand feet above the level of the sea, the water in the basins was usually frozen to the very bottom, so as to admit of being thrown out in the morning a solid mass; whilst some estimate of the dryness of the climate may be formed from the fact that a flame of electricity was emitted on even hastily raising the quilt from the bed. This was first pointed out to me by a native Indian servant in September at Caubul, who fancied the bed was on fire when he went to make it down; but it continued afterwards to be observed, more or less, till we finally left the country in the end of November.

Pleuritis.—Of this we can only remember three well-marked cases which could fairly be said to have originated within the Tropics, and our reasons for assuming even these to have been idiopathic are by no means unequivocal; whilst the non-proclivity to such diseases in these climates may be deduced from the fact of the immediate disappearance of the pleuritic complications on our leaving Scinde for Bombay in March 1840, and still more so from the improvement, under the most unfavourable circumstances, of three of these cases embarked with the right wing of the 17th Regiment. Though we were

shipwrecked and cast ashore, not only without tents or other covering, but many even minus part of their ordinary clothing, and drenched in salt water, without medicine, and for some days almost without food, they did not die, as we had anticipated, but continued to convalesce almost as if there had been no such occurrence. They did not finally recover as the others, it is true, but they were still improving when we left the regiment about the 1st of October.

Bristol, August 23, 1850.

POISONING WITH SECALE CORNUTUM.

DR. PRATSCHKE was called on the 12th October, 1844, to a woman who, with her three children, had been taken ill the day before. Five days previously they had eaten bread which contained a large proportion of blighted corn. The mother, forty years of age, complained of uneasiness and heaviness in the head, oppression at the stomach, loss of appetite, and diarrhoea; but she did not feel ill enough to take to her bed. The eldest daughter, eighteen years of age, complained of a violent sense of burning in the hands and feet, and especially in the fingers and toes, which were bent and stiff. The lips were retracted so as to expose the teeth; the tongue white and moist; the skin dry and cool; the pulse 90, and small: the patient was very restless, and expressed urgent thirst; the abdomen was soft; the bowels acting; the urine pale. She died on the following day in violent convulsions.

The second daughter, seven years old, had the same affection of the lower extremities, which in her case occurred periodically: her appetite was good: she had also diarrhoea.

The third child, four years old, suffered only from diarrhoea.

An emetic was given to all in the first place; camphor was afterwards administered.

The mother suffered for a few days from tetanic cramps, and continued to complain of great anxiety, loss of appetite, and diarrhoea. After the exhibition of valerian, muriate of ammonia, and ipecacuanha, followed by extract of nux vomica, these symptoms disappeared, but were succeeded by anesthesia of the soles of the feet.

The second daughter was restored to health, with the exception that she had not perfectly recovered the use of her legs.

The youngest child suffered from tetanic cramps for several days; and considerable stiffness of the limbs remained, so that she frequently fell in walking. This subsided under the use of aromatic baths.—*Casper's Wochenschrift.*

X

MEDICAL GAZETTE.

FRIDAY, OCTOBER 4, 1850.

WE have hitherto delayed noticing the letters which have recently passed between the Home Secretary and the Royal College of Surgeons, under the supposition that the correspondence would be continued. It seems, however, that the subject has been allowed to drop, and the Medical Reform question is again *in statu quo*. Still there are some points in the questions of the Home Secretary and the replies of the College which call for notice at the present time; and it is to these that we shall now direct our attention.

Sir George Grey objects to that resolution of the College which excludes from eligibility to the Council, every fellow who resides at a greater distance than *five miles* from the General Post Office, or who practises, or has within *five years practised pharmacy*, either directly or indirectly. He tells the College that these two conditions, if carried out, would create much dissatisfaction.

It will be perceived that the disqualification refers to *distance* as well as to the *practice of pharmacy*. We subjoin an extract from the reply of the College as to the ground of disqualification from distance:—

"In reconsidering the provision of the present charter, which excludes from the Council 'every fellow of the College who resides at a greater distance than five miles by highway or road from the General Post Office at St. Martin's le-Grand,' the Council see no reason to recommend any alteration therein. They are of opinion that fellows 'actually practising their profession' could not perform the duties which devolve upon them as members of council should their residences be at a greater distance from the metropolis; and they beg to remind Secretary Sir George Grey that

a seat in the Council is not a mere honorary distinction, or that it requires only regular attendance at stated meetings of the Council, but that a large amount of the business of the College is necessarily transacted in committees, and that the meetings, both of the Council and of committees, are often the result of unexpected calls. The meetings of Council during the past year have been no less than twenty-two; and the meetings of committees during the same period have amounted to thirty-four. From this statement it will be evident that the exclusion, which, it is presumed, will cause dissatisfaction, arises simply from the fact that fellows of the College residing at a distance from London cannot perform the duties which devolve upon them as members of Council: and it is quite clear that there is no assignable reason for excusing them from the duties which they would be bound to fulfil."

The resolution of the College is, as it is stated by the Secretary, merely a copy of the tenth article of the charter granted in 1843, upon the recommendation of Sir George Grey's predecessor. This article also includes the disqualification respecting the practice of pharmacy and midwifery; and the only difference in the late resolution to which the Home Secretary objects is, that the practice of midwifery shall not in future render a fellow ineligible. As this charter has now been in operation seven years, it is really a question whether the tenth article in its practical working has given rise to that dissatisfaction which Sir George Grey predicts as likely to follow from the provisions of the resolution. Either the Home Secretary has entirely forgotten the articles of the charter now in force, or he has stated his objection to the late resolutions, which are conceived in a more liberal spirit, in a very obscure manner.

We think that the two grounds of disqualification—*distance* and the *practice of pharmacy*—should be held distinct. The former would, undoubtedly, have the effect of excluding good provincial sur-

geons, who might do honour to the College; and promote as much as metropolitan fellows the advancement of surgical science. As *amici curie* in this matter, and without any desire to take a prejudiced view of the question, we do not see why, in a Royal College of the kingdom, the provinces should not be represented as well as the metropolis. The objections of the College affect merely the position of the elected member; and they may be reduced to this. If a surgeon lives beyond five miles it is impossible to give him due notice of the meetings of Council, Committees, &c.; and the distance at which he resides would be an obstacle to the punctuality of his attendance and the regular transaction of business. The College assert that provincial surgeons thus situated, could not perform the duties which would devolve upon them as Members of Council, and proceed to argue that there is no assignable reason for excusing them from the duties which they would be bound to fulfil. In these days of railways, electro-telegraphic and postal communication, these reasons appear to us insufficient to justify the exclusion of fellows on the ground of distance. Many provincial members might easily attend at twenty-four or forty-eight hours notice, and the electric telegraph might be used in cases of such extreme emergency as those suggested by the Council. The College might, therefore, fairly and reasonably abandon the objection on the ground of distance; and thus satisfy the profession that there is no desire to monopolize for the metropolitan fellows only, all power and control over the surgical profession in England and Wales. They have in their hands a very simple remedy for neglect of duty on the part of members when once elected—namely, that if any member, whether metropolitan or provincial, absent himself from a given number of meetings of Council or Com-

mittees, except on the ground of illness or other sufficient cause, distance of residence from London not being admitted a sufficient excuse, he shall cease to be a member of Council, and a new election take place. At present, the Collège, without having made a trial, contend that a provincial surgeon cannot perform the duties of a Member of Council: the provincial practitioners, on the other hand, in expressing their dissatisfaction through Sir George Grey, assert that they can perform these duties. As there is a clear and reasonable remedy in the hands of the College, if their view should prove to be correct, we really do not see why this disqualification on the ground of distance should not be at once surrendered. We do not think that the concession could in any way whatever affect injuriously the interests of the College; and, according to Sir George Grey, one of the causes of dissatisfaction would be removed.

The other disqualification—*i. e.*, the *practice of pharmacy*—is based on totally different grounds. In a Royal College of *Surgeons*, founded especially for the promotion of the science of *Surgery*, it would, we believe, be an unprecedented course to admit to membership of Council, and thereby to a complete control over the affairs of the College, those members or fellows of the College who practise pharmacy either directly or indirectly. This rule of exclusion is, we believe, strictly enforced in the Royal Colleges of Surgeons in the sister countries of Scotland and Ireland; and we ask why the *English* College is to surrender its privilege on this subject, when such a demand is not made, and could not reasonably be made, of the other two British Colleges. Sir George Grey states in his letter that this disqualification creates much dissatisfaction. We should like to have in "facts and figures" a statement of the number of members of the College of

Surgeons who have expressed their dissatisfaction with the arrangement now in force and proposed to be continued. A statistical summary of the profession, in England and Wales, published in our last volume,* shows that there were practising throughout the country in 1849, about 5000 members of the College of Surgeons, including 1127 who had no other qualification than that membership. Have even 2000 of these members recorded their dissatisfaction at the Pharmacy clause of the old charter, and its continuance in the new one? We do not believe that one-half of the members would wish to see a new College founded, merely because fellows of the old College, who practise or have practised pharmacy within five years, are not eligible to seats in the Council. There may be a difference of opinion about the number of years of cessation from this branch of practice. Some may think one or two years sufficient; but we believe that the majority of English members will be found to adopt the view that it would be unjust and unfair to force upon the English College rules of government which do not exist in the Scotch and Irish Colleges of Surgeons, and which, in our opinion, could not safely exist in any College intended for the special cultivation and improvement of *surgery*. We fear that those who would thus forcibly alter the constitution of the English College are really desirous of indirectly overthrowing it. Let the question be considered in this light: the admission of pharmaceutical surgeons to seats in the College Council would probably amount to no more than a small minority out of twenty seats. In this case nothing whatever would be gained by a removal of the disqualification. On the other hand, these members might gradually acquire a majority in the Coun-

cil, and then the College of *Surgeons*, as such, would cease to exist. With the present mode of election, the former alternative would be the more likely to come into operation under the change. The votes and voices of two or three fellows practising pharmacy would be drowned in the wishes of the surgical majority. The consequences may be easily predicted: there would be an immediate resolution that the interests of general practitioners were not attended to, and that some alteration in the mode of election and in the right of voting was indispensably necessary. In fact, the members of this party would not be contented until they had attained, in one way or another, a majority in the Council. Let our readers rest satisfied: it is a mere struggle for power. The admission of three pharmaceutical fellows to the Council would certainly not remove that dissatisfaction which is said to exist, when, as it would happen, their votes were invariably neutralised by seventeen opponents. It is not simply an eligibility to seats in the Council that is desired, but an absolute and despotic control over the affairs of the College. The surgical profession would be merely exchanging what is now pronounced to be one form of despotism, for another which it is our belief they would find far less bearable.

We cannot agree in the assumption that the interests of general practitioners are, as it is alleged, entirely neglected in the Charter as at present constituted. A Fellow of the College who has desisted from practising pharmacy for five years is eligible to a seat in the Council. Is it to be assumed that such a Fellow has lost all consideration for his brother practitioners, merely because he has retired for a few years from this laborious branch of practice? Is a general practitioner of thirty or forty years' standing, if he desist from the practice of phar-

* Vol. xiv. page 567.

macy for five years, so completely transformed into a "pure" surgeon, that he has lost all interest in the concerns of his former fellow-labourers in the profession? It may be said that under the present mode of election such Fellows would stand no chance of obtaining seats in the Council, when they had to compete with men who had devoted themselves through life to the practice of surgery only. We decline to admit the imputation which such an assertion would throw upon eight hundred educated gentlemen, until it has been clearly proved that one who was fully qualified for a seat had been set aside for another who had no other claim over his competitor than that he had never practised pharmacy. A large number of the Fellows practise or have practised pharmacy, and we believe that they would successfully resist any attempt to coerce their wishes on this point.

On this part of the question the reply of the College is, we consider, most satisfactory. They tell the Home Secretary that this rule of exclusion already exists under the Charter of 1843, and contend "that those who have established the proof of their especial and successful devotion to the study and practice of surgery are best fitted to act collectively for the advancement of surgical science, and therefore best qualified to be entrusted in a collegiate capacity with the functions of superintending the education, and of conducting the public business, of the surgical profession." The only question open for the reconsideration of the Council on this subject is, whether a cessation from pharmaceutical practice for *one or two*, in place of *five years*, might not meet all the requirements which they deem necessary for maintaining the surgical character of the College.

Another subject on which the Home Secretary desires information is com-

prised in the following extract from his letter:—

"While the Council proposes certain alterations in the Charter of the Royal College of Surgeons with reference to members of the College, they do not state any clear proposition with regard to that class of medical practitioners *not members of the College*, who have been termed general practitioners, and whose incorporation forms one part of a scheme which has been strongly pressed."

In all new acts or charters there should be no retrospective injustice; but we take this inquiry on the part of the Home Secretary to involve a most singular want of acquaintance with the real state of the medical profession. A regularly qualified medical practitioner, or "general practitioner," we understand to be one who has the diploma of the College and the license of the Hall. Of these there are in England and Wales 4633.* There are some members of the Scotch and Irish Colleges, and 1038 Licentiates of the Society of Apothecaries, who are not members of the English College, but who practise, and are known under the name of "general practitioners." As to the Scotch and Irish members, we think there would be no difficulty in their admission to the membership of the English Colleges on an *ad eundem* principle, if it could be shown that they had received a *surgical* education and had been *examined in surgery*. The same remark would apply to graduates of the Universities of Edinburgh and London; but with regard to the licentiates of the Apothecaries' Society who can produce no test of their having received a surgical education, or of their having been examined in surgery, the case is widely different. That they should claim the membership of the College as a matter

* See our last volume, p. 667.

of course, would not only be fraught with injury to the public, but with injustice to the 5000 gentlemen who have taken out the double qualification. They may, it is true, have studied and practised surgery, and have termed themselves general practitioners; but in what respect, so far as a *qualification in surgery* is concerned, do they differ from one who has not even the license of the Hall in his possession? We intend no disrespect to those members of a useful body who have entered into practice with an Apothecaries' qualification only, but we assert that in any future legislation they have no more right to be enrolled as "surgeons" than the members of the Royal College of Surgeons have to be enrolled as licentiates of the Royal College of Physicians, or M.D. graduates of Oxford, Cambridge, or London. If this general admission is to take place, irrespective of any inquiry into *surgical* education or examination on the part of the claimants, merely because they have for some years practised surgery with an Apothecaries' license, and have been loosely designated "general practitioners," then we do not see how the many unqualified persons who infest the country, but who have also practised surgery for some years, are to be excluded from the enrolment. Under any reform measure, the licentiates of the Apothecaries' Society might as reasonably claim to be placed on the roll of the College of Physicians as on that of the College of Surgeons; and indeed with greater plausibility, because they have received a *medical*, and not a *surgical* education.

If the suggestion involved in the inquiry made by the Home Secretary were to be carried out, *surgical* education should from this moment cease throughout the country. The curriculum of the Apothecaries' Society is less costly than that of the College; it requires no attendance at lectures on surgery or on

surgical practice; it involves no examinations on this important branch of the profession; and of what profit would it be to a student to make this additional outlay, and prepare himself for a College examination, when with the Apothecaries' license he may term himself a general practitioner, and hereafter claim to have his name enrolled among *surgeons* on the College list? It would be a gross injustice and a positive injury to the profession to hold out to young men the expectation that the license of the Hall shall *de jure* entitle them to the rights and privileges of members of the College of Surgeons.

If, then, the inquiry be made, in what relative position all gentlemen now "terming themselves" general practitioners are to remain, we reply, let their present rights and privileges be intact. They who had received no surgical qualification might retain the same position with regard to the College of Surgeons as that which was assigned by the Apothecaries' Act to gentlemen in practice before 1815. Those who had the double qualification would of course be enrolled as members of the College. It is greatly to be regretted that such a system has been permitted to grow up, as that men with a license for one branch of the profession should have been allowed to practise another on which their qualifications had not been tested. It is an evil which has long since required correction: and had this been attended to, the Home Secretary would not now have had to ask in what position the College of Surgeons intended to leave those practitioners who had no surgical diploma, and who had given no proof of having received a surgical examination.

Reichetes.

Researches on Magnetism, Electricity, Heat, Light, Crystallization, and Chemical Attraction, in their relations to the Vital Force. By KARL BARON VON REICHENBACH, Ph. Dr. Translated and edited, at the express desire of the author, with a Preface, Notes, and Appendix, by WILLIAM GREGORY, M.D., F.R.S.E., Professor of Chemistry in the University of Edinburgh. Parts I. and II., including the second edition of the First Part, corrected and improved. 8vo. pp. 468. London: Taylor, Walton, and Maberly. Edinburgh: Macleachlan and Stewart. 1850.

Physico-physiological Researches on the Dynamics of Magnetism, Electricity, Heat, Light, Crystallisation, and Chemistry, in their relations to Vital Force. By BARON CHARLES VON REICHENBACH. The complete Work from the German second edition, with the addition of a Preface and Critical Notes, by JOHN ASHBURNER, M.D. 8vo. pp. 290. London: Baillière. 1850.

THE very full notice we gave of Baron von Reichenbach's researches at p. 911 of vol. ii., new series, has put our readers in possession of the novel character of his discoveries. In order to save them the trouble of reference, and ourselves the space which would be occupied by going over the subject again, we may quote the following passage from that review:—

"Our readers must not suppose from the title, that this essay is written in support of mesmeric quackery. It is true, that many of the results obtained by the author appear to establish the existence of a new imponderable capable of affecting inorganic and organic, or dead and living, matter; possessing, according to his experiments, powers of conduction, isolation, refraction, polarization, and diffusion, and endowed with dualism, according to laws which are as yet imperfectly ascertained. This force or power is, however, wholly distinct from magnetism in its properties: it does not attract iron, nor is it influenced by terrestrial magnetism. . . . This force is found to reside in powerful magnets; for it is stated that, when these are drawn along the living body downwards without contact, they are found to produce certain sensations in a certain proportion

of human beings, whom the author calls *sensitive*."

This extract presents as closely as possible the substance of the first part of Reichenbach's researches, as set before English readers by Dr. Gregory's translation in 1846. The volume now before us contains a second edition of the former researches, and comprises a more detailed account of the experiments whence those results were deduced, than it was then thought advisable by Dr. Gregory to place before the British scientific public: with this are joined investigations which have been subsequently published in Germany by Baron von Reichenbach.

Dr. Gregory remarks in his preface, that although in this country the scientific press has received the startling and novel statements of the author with "that respectful and becoming attention to which, from the known scientific reputation of its author, it was justly entitled,"—a reception different from the irrational and unwarrantable attacks they met with in Germany,—yet that he has occasionally, in private, "met with persons disposed, like the German critics, to reject the whole investigation, without even giving it a careful study, or indeed any study at all."

With such persons we have certainly no sympathy; neither should we feel disposed to bestow upon them the argumentative remarks by which Dr. Gregory has endeavoured, in his preface, to convince them that no well-ascertained facts, or series of facts, can possibly exist in nature which are not worthy of our earnest study.

The second portion of Reichenbach's researches is directed to the investigation of the magnetic or "odylic" light; and, to give our readers an idea of the author's experiments, we quote the following passage from his "Introduction":—

"It has been objected to me that the five girls, whom I have chiefly employed as my reagents for the new force, are not sufficient, where the object is to establish, with a certainty, important truths in natural science. I proceeded to act on this principle, and exerted myself to extend my investigations over a greater number of persons, in various states as to health, and in various conditions of life. In this way more than two years have been employed, and to that extent the following treatise, containing a detailed investigation into the

properties of the odyllic light, as exhibited by magnets, has necessarily been delayed. But it now appears with a train of NEARLY SIXTY SENSITIVE PERSONS AS WITNESSES, male and female, mothers and maidens, low and high, poor and rich, feeble and vigorous, diseased and healthy, women during menstruation and during pregnancy; and thus we have representatives of so great a variety of physical conditions, that little more can be desired."

The author gives a list of the names of the sixty persons "who have assisted him by their observations, and supported him with their sympathy during his researches, and who possess the power, in different degrees, of observing the peculiar phenomena, the study of which is the object of this work." Among these we find twelve individuals, designated as "physicians," "natural philosophers," &c., engaged in scientific occupations; besides lawyers, clergy, &c.

The author states, with reference to the term *odyle*, "that the idea expressed by it very probably includes that which, a year later than I, Dr. Faraday introduced to the scientific world as a new force under the name of Diamagnetism," observing at the same time, that the British philosopher was not acquainted with his researches.

It is important to state the affinities and the differences between *odyle* and magnetism, as recorded by the author.

"*Odyle* is produced and vividly manifested in a multitude of cases in which magnetism, properly so called, is nowhere observed, or is yet unknown to exist,—as in part during chemical changes, in vital changes, in crystals, in the case of friction, in the spectra of solar and lunar rays, and of candle-light, in polarized light, and in the amorphous material world generally."

"In the vast majority of cases *odyle* is developed alone without magnetism. Magnetism never appears alone, but is always associated with *odyle*."

But we must here remark that it should not be lost sight of, that chemical action is always attended with electrical changes,—a fact familiarly exhibited in chemical lectures, and demonstrated by the daily use of the galvanic battery.

The experiments detailed in this part of the work are too minute and too numerous to permit of our giving even an abstract thereof: we shall be obliged to confine ourselves to the enumeration alone of the recorded results.

The *odylic* light is stated to have been perceived by "healthy sensitives," by "delicate or sickly sensitives," by "diseased sensitives," individuals of each of which classes, on whom the experiments were made, are mentioned by name. The *odylic* light appeared to these variously, as—1, a glow; 2, flames; 3, threads, fibres, or feathery down; 4, luminous vapour or smoke; 5, scintillation. The characters and behaviour, under varying circumstances, of these several forms of the light, are fully described by the author.

The author considers the *odylic* light to be "nothing else than the same phenomenon which, on the great scale, appears as the *aurora borealis*, or rather as the polar light, south as well as north." The following extract will give the grounds of this opinion, and at the same time will furnish an idea of the alleged phenomena:—

"Now that we know from the preceding researches that flaming lights exist over magnetic poles larger than the magnets from which they flow; when we learn that these flaming appearances are moveable, undulating, often moving in serpentine windings,—like those of a ribbon agitated by the wind,—becoming at every moment larger or smaller, shooting out rays, scintillating, variegated in colour, and often nebulous, vaporous, and cloud-like; when we find that with our breath we can cause it to flicker backwards and forwards; when we observe that it increases in a rapid ratio in size, intensity, and brilliancy, in rarefied air; and, lastly, when we see it followed at every step by the play of rainbow colours, &c. &c.,—there remains hardly one essential mark of distinction between magnetic light and terrestrial polar light, unless we regard as such the difference of intensity and amount of light, in virtue of which the polar light is visible to every ordinary eye; the magnetic light only to the sensitive eye" (p. 446).

Dr. Gregory, in his Appendix, confirms the Baron's statements by his own observations in several cases.

Dr. Ashburner's translation of Baron Reichenbach's *Researches* "owes its existence perhaps to one, perhaps to a series of misapprehensions with which the public have little concern." These appear to be connected with the publication of his translation without communication with Dr. Gregory; but as we are a part of the public, we have, of course, no concern with these misappre-

hensions The subjects contained in his work are necessarily the same as those contained in Dr. Gregory's edition, but somewhat abridged. Dr. Ashburner presents us more immediately with the results of Baron Reichenbach's "Researches;" but his translation is deficient in the extent of detail as regards experiments: on this part of the subject Dr. Gregory's translation is very full.

It is probable that the publication of these two treatises may lead British philosophers to examine for themselves a series of phenomena hitherto but little observed, and which, from their marvellous character, have as yet only excited distrust or incredulity.

An Inquiry, How far Consumption is Curable; with Observations on the Treatment, and on the use of Cod-liver Oil, and other remedies; with Cases. By JAMES TURNBULL, M.D., Physician to the Liverpool Infirmary, &c. 2nd edit. enlarged, 8vo. pp. 106. London: Churchill, 1850.

THAT Consumption, by which we understand tubercular phthisis, when once undoubtedly developed, is incurable, is an opinion that obtains very generally, there can be no disputing. Whether this opinion be rightly formed or not is certainly worth inquiring: there can be no doubt of its practical importance as to treatment, if the result be an affirmative answer.

We shall place before our readers an abstract of the evidence upon which Dr. Turnbull arrives at the affirmative conclusion of the curability of consumption, and we shall notice the extent to which this curability is attainable by remedial measures.

Dr. Turnbull observes:—

"The evidence in favour of the curability of tubercular disease of the lungs is derived from several sources. By inquiring of our patients closely into the history of previous attacks of illness affecting the chest, we occasionally find that at some period they have had many of the symptoms of consumption, and yet have recovered. This alone is the least important kind of evidence, but it becomes valuable when supported by some of the other kinds. Observation of the symptoms, in cases which come under our treatment, and get well, stands next in value. The examination of the chest with the stethoscope and by percussion, when the disease has ad-

vanced to a certain length, conveys to those who are well acquainted with these modes of examining the chest most satisfactory evidence of the condition of the lungs during and even after recovery. The last kind of evidence is visible and palpable, and cannot, therefore, be doubted: it is derived from an examination of the lungs after death" (p. 13).

It is undoubtedly required that all these kinds of evidence, excepting the last, be combined in a single instance before it can be admitted, during life, that a case of consumption has been cured. Dr. Turnbull speaks of those who reject the evidence furnished by the use of the stethoscope. We count their objections as equal to nothing.

Dr. Turnbull quotes Bayle, Laennec, and Andral, with reference to the recurrence of cicatrization of cavities, and dwells upon the notices of the fibrous and cretaceous transformations of tubercles, and healing of cavities, to be met with in various authors, and which are well known to all engaged in necroscopical examinations.

The author in the next place quotes the statistics of Dr. Walsh, which show that complete restoration to health, not only as regarded the symptoms, but also local evidence of active disease, was effected in 4.26 per cent. of his cases. The Report of the Hospital for Consumption states that the most favourable results have been obtained in the first stage of the disease, since nearly one-half in this stage were relieved, and in ten per cent. all symptoms had disappeared, the patients feeling themselves well, and being able to follow their ordinary occupations. The disease was arrested in two out of fifty-three cases in the second stage; and in ten out of two hundred and ninety-five in the third stage.

Such is the evidence from pathology which Dr. Turnbull adduces in proof of the curability of consumption; and such, we may remark, has long been admitted. The facts adduced afford conclusive evidence of the possible occurrence of so desirable a consummation.

Dr. Turnbull in the next place furnishes us with evidence from therapeutics, and enumerates several remedies which he has found beneficial: among these cod-liver oil is the chief. The Report of the Hospital for Consumption, and Drs. Williams and Bennett, are

also quoted with reference to the efficacy of cod-liver oil. A series of cases of cure is given in illustration of the beneficial influence of cod-liver oil over tubercular disease. But, at the same time, it must be observed that other treatment was found requisite in all cases, especially such as ministered to the improvement of the general health. Great care was taken with reference to diet and exercise, and in some cases the patients enjoyed the advantage of Sydenham's *palmarium* remedy, horse-exercise.

Dr. Turnbull has brought together a sufficient number of facts to encourage us to hope that success may in some instances attend our efforts to arrest this generally incurable disease, by the use of remedies. The author appears, however, more sanguine than the number or character of his facts warrants; but his publication may be of service by inducing fresh efforts at the hands of others.

Memoir on the Influence of Hypertrophy and Dilatation on Diseases of the Heart; and on some Points in their Diagnosis and Treatment. By A. HALLIDAY DOUGLAS, M.D., Fellow of the Royal College of Physicians, Edinburgh; Physician to the Royal Infirmary, Lecturer, &c., &c. Pamphlet, 8vo. pp. 49. Edinburgh: Sutherland and Knox. 1850.

THIS memoir consists of a series of cases and observations, which have appeared in the Edinburgh Monthly Journal of Medicine; and are arranged under five sections.

1. Hypertrophy and Dilatation; 2. Aneurism of the Heart; 3 and 4. Contraction of the Valves; 5. Incompetence of the Valves.

With reference to the first section we may extract the following passage, as embodying very much of the gist of the author's opinions with respect to diseases of the heart:—

"Dilatation has been esteemed dangerous, chiefly because believed to indicate that obstruction of the circulation has been extreme; and the cause of that obstruction from which the dilatation arose has been regarded as the cause of all those secondary evils and distresses which so invariably occur in the last stage of cases of disease of the heart. Now, I think that an error has been committed here, and that the dilata-

tion exerts a material and direct influence in the development of these secondary evils, while the pre-existing cause of obstruction, whether it be valvular or other is comparatively unimportant, except in so far as it must be regarded as the origin or commencement of a series of changes which is to result so formidably. In short, while dilatation is *secondary* in regard to the period of its development, it becomes *primary* in its ultimate importance, acting as the *chief* cause of all the most dreaded evils of the diseases of the heart." (p. 1.)

This quotation contains the leading object of the memoir, which is to show the supreme importance of hypertrophy and dilatation, especially the latter, in the diseases of the heart; at the same time it points out their frequent, if not invariable co-existence, and their relation to valvular disease.

The cases are carefully selected, and well reported. The accompanying observations form a useful practical commentary on some forms of disease of the heart. We commend this essay to all clinical students as containing matter that they will find of service in their studies.

DANGER ATTENDING THE USE OF CHLOROFORM.

DR. HAYWARD, U.S., who is evidently a strong advocate of the use of ether, says, "I am satisfied that there are already on record at least twenty well-authenticated cases of death from the inhalation of chloroform; and I know not how a conscientious man, knowing this fact, can willingly take the responsibility and expose his patient to this fearful result. One of the conclusions to which M. Malgaigne arrives, in his report on chloroform, to the Academy of Medicine of Paris, cannot be too strongly impressed on the minds of those who feel inclined to use it. 'Chloroform possesses a toxic action peculiar to itself, which has been taken advantage of in medicine by arresting it at the period of insensibility, which action however, may, by being too much prolonged, cause immediate death.' The danger is, that we cannot always know the precise time to arrest it, and that the fatal blow may be struck before we make the attempt. In other words, chloroform is a poison, and the insensibility which it produces is only the first stage of its poisonous action."—*American Journal of the Medical Sciences*, July 1850.

Proceedings of Societies.

ACADEMY OF MEDICINE, PARIS.

Sept. 10 and 17, 1880.

Cholesteritis—Scintillations of the Eye.

M. DESMARRES stated in a note, that in several patients suffering from scintillations he had extracted minute floating bodies from the anterior chamber of the eye, and had found them to consist of cholesterolina. Conceiving the symptoms, therefore, to depend upon a morbid state of the secretions of the serous membranes of the eye, he had given to the cases the name of *cholesteritis*.

Chemical Tests of Cerebral Matter.

M. LASSAIGNE informed the Academy that, on repeating Orfila's interesting experiments,* he had been enabled to add one more to the chemical characters of cerebral matter indicated by Orfila—viz., the formation of phosphoric acid by the calcination of cerebral substance in the air.

Extirpation of a Bronchocele.

M. ROUX related a successful case of extirpation of a goitre, which he had performed two months ago. The patient was a strong, healthy man, 30 years of age. The tumor had existed between twelve and fifteen years, and had attained the size of a large fist. It extended more on the left than on the right side, reached above to the os hyoides, below to the sternum and clavicle, and was prolonged a little behind the latter bone. It was scarcely moveable, being firmly attached to the larynx. The carotid artery was not in connection with the tumor.

The operation was only undertaken at the urgent desire of the patient. It was performed in the presence of MM. Rigal, Sautin, and Gerdy.

The tumor was exposed by a long vertical incision extending from the os hyoides to the sternum, and was removed without any difficulty. The vessels tied were numerous; but little blood was lost; syncope did not occur. At one moment during the operation the patient experienced severe dyspnoea with aphonia: this was apparently caused by the section of the recurrent nerves, as the voice has since remained feeble and hoarse. Recovery took place rapidly, the vertical cicatrix being the only remaining trace.

The tumor weighed 325 grammes (=

4975 gra., or about 10 oz. Eng.). Its larger or vertical circumference measured from 27 to 28 centimetres (= about 11 in. Eng.): its transverse measurement was 23 centimetres (= 8.617 Eng. in.).

Use of Chloride of Sodium in Ague.

M. PIORRY stated that, among the various remedies he had investigated as substitutes for cinchona, he had found none exert so decided an influence on enlargements of the spleen as chloride of sodium. This influence had been witnessed in eight cases. In several instances two doses had sufficed to reduce the spleen to its normal dimensions.

New Application of Apparatus termed Hydrophora.

M. FOURCAULT read a note relating to certain apparatus introduced by him some time since for the purpose of applying dry heat and anhydrous cold to all parts of the body in the treatment of internal and external disease, and also as a mechanical means of rendering women barren.(!) The particular modifications of the instrument submitted on this occasion by M. Fourcault were the uterine and the vaginal hydrophora. These instruments being constructed of vulcanized caoutchouc, form a cul-de-sac which is connected with a syringe, by means of which a double current of cold water can be introduced into the vagina or uterus without coming into actual contact with the mucous membrane. By an adaptation of the principle of this apparatus to the caoutchouc pessary provided with a diaphragm of gutta percha, caoutchouc, or of some soft spongy substance, M. Fourcault has contrived the means of presenting a voluntary obstacle to fecundation!

Sulphuret of Arsenic in Mineral Waters.

M. BLONDEAU stated that he had discovered sulphuret of arsenic in all mineral waters possessing energetic properties.

The Phosphene or Luminous Spectre produced by Compression of the Globe of the Eye, an Indication of the Condition of the Retina.

M. SERRÈS (of Alain) transmitted the first part of a memoir in which he proposes to regard the luminous spectre produced by compression of the eye as an indication of the state of functional life in the retina, and to apply the information thence ob-

tained to the diagnosis of diseases of the eye. M. Serres produces the *phosphene* by pressing with a hard angular body, repeating the pressure at least twice in a second of time. The nasal aspect of the globe is the part of the organ preferred by M. Serres, as he has usually found the luminous spectre more brilliant than when pressure is made on other parts of the globe. If, after repeated trials made during several days, no luminous spectre is thus produced, paralysis of the retina may be inferred, and thence the conclusion that operations on the cornea, iris, or lens, will be useless.

Poisonous Action of Agents protective of Dead Animal Matter against Spontaneous Combustion.

M. ROBIN communicated a memoir on this subject, of which the following observations constitute a summary:—

All those agents which protect dead animal matter from slow combustion by oxygen with moisture, are poisonous both to plants and animals; and they are so, not by their direct action on the nervous system or heart, nor by the coagulation of albumen, but by their opposing during life, as well as after death, the slow combustion of animal matters by oxygen.

Every agent possessing this power, if introduced in sufficient dose into the circulation, in the same manner prevents the oxidation of the protein elements of the blood, and thus produces a sedative poisonous action, or causes death by asphyxia.

Those agents which exert this protective power in the highest degree are in general the most active poisons.

The poisonous action of many substances which is exerted in this way (*e. g.* hydrocyanic acid, the ethers, chloroform, camphor, benzoin, arsenic) has been attributed to a direct action on the nervous system. This assertion M. Robin regards as gratuitous, and considers that the chemical action to which he refers, being in strict relation with the phenomena observed during life and after death, affords a more correct explanation of their mode of action.

MONTPELIER ACADEMY OF SCIENCES.

On the Preparation of Collodion. By M. F. LUTRAND.

AFTER some introductory remarks on the value of collodion, M. Lutrand states that he has made a great number of experiments with the view of ascertaining the best for-

mula for the preparation both of the cotton and the ethereal solution.

Preparation of the cotton.—M. Lutrand recommends that the cotton should be placed in a mixture of suitable proportions of dry nitrate of potash, concentrated sulphuric acid, and fuming nitric acid. In this way he unites the two processes generally employed—*vis.* that of Kopp, who uses a mixture of monohydrated nitric acid and concentrated sulphuric acid, and that of Mialhe, who employs a mixture of nitrate of potash and sulphuric acid. In this case the sulphuric acid exerts a two-fold action: first, it seems to decompose the nitre; secondly, it keeps the nitric acid in a monohydrated state: the cotton imbibes the acid more readily, and the prepared cotton offers greater uniformity of composition throughout its whole mass.

Preparation of collodion.—M. Lutrand states that the two formulæ generally employed in the preparation of collodion are those of Mialhe and Bouchardat. That of Mialhe gives too firm a product; whilst that of M. Bouchardat, on the contrary, is too fluid. M. Lutrand recommends a combination of the two processes. Instead of using for every 1000 parts of ether 64 parts of prepared cotton, as recommended by Mialhe, or only 22·37 parts, according to the formula of M. Bouchardat, M. Lutrand employs 32 parts, or one half of the proportion indicated by M. Mialhe, with the addition of 80 parts of alcohol.

FRACTURE OF THE NECK OF THE HUMERUS.

A MAN, 75 years old, fell from a stool and broke his arm. Two months afterwards he died. An examination of the limb showed that the fracture had taken place close to the head, and that reparation had made but little progress. The capsule of the joint was filled with sanguineous gelatinous fluid. The space between the fractured surfaces was occupied by a cartilage half an inch thick, around which the periosteum formed a capsule so firmly attached that it was with difficulty separated. Beneath the periosteum, around the bone, was a callus-like capsule, which gradually united with the new cartilage. This capsule of provisional callus exhibited, under the microscope, the fibres of the periosteum connected with new osseous cells; separate points of ossification could also be detected. The attempt at union was demonstrated in a circle of earthy deposit around the end of each bone.—*Casper's Wochen-schrift.*

FELLOWS' PRIZE ESSAY.

Summer Session 1845.

By C. H. F. ROUTH, M.D. Lond.

[Continued from p. 491.]

PART II.

IN the pursuit of the inquiry as to whether excess of urea is ever passed in 24 hours, it became important to ascertain by actual experiment whether a given quantity of urine contained such excess. For the most part specimens of high specific gravity were selected, and the rough test applied to them.

Several tubes of the same size were procured. An arbitrary measure was taken of 48 minims. One half, or 24 minims, were tested with an equal quantity of nitric acid, and, the tube being kept in a glass of cold water, set aside to crystallize. At the end of 24 hours the quantity of urea so obtained was collected, dried, and weighed, and then, by the simple rule of three, the amount of urea passed in 24 hours calculated.

The experiments were made upon 52 cases, in which the specific gravity varied from 1021 to 1039. In many, however, of these cases no crystals of nitrate of urea were found. This was the case with one of delirium tremens especially, with a specific gravity of 1039, while in others of much lower specific gravity the quantity so formed was very considerable. The inference necessarily was, that, as far as the rough test was concerned, it was not to be depended upon. In comparative experiments we were enabled to make out four causes of this:—

1st. If the water in which the tube was placed was not of a certain low temperature the crystallization did not occur. The difference of temperature in the water, even when placed under the same circumstances, was found to vary as much as 10° F.—usually 5°; and this was sufficient to determine a great difference in the amount of crystallization.

2d. Excess of colouring matter seemed to prevent the determination of the crystallization, especially when the colour was of a red amber; but at other times no such connection could be traced.

3d. Liebig has shown that if to a solution of urine which is very full of lithates nitric acid be added, a portion of the uric acid is decomposed, and nitrate of urea formed in the combination. Such a complication would generally (in the cases selected) vitiate the result.

4th. The nitric acid is liable to vary in strength and kind. If very concentrated, and especially if containing in solution the slightest quantity of peroxide of nitrogen, it at once determines the decomposition of the urea.

a. A knowledge of these sources of fallacy at once satisfied us that no data so obtained could be relied upon, and analysis was therefore had recourse to in every case in which it appeared probable *a priori* excess of urea was passed in the 24 hours.

b. The next consideration referred to the best method of analysis. It may be well here, therefore, to enumerate each process which we tried, enumerating in the description the several difficulties and sources of fallacy in each.

1st. *Oxalate of lime process*.—1. A given quantity of urine is taken. This is evaporated to the consistence of a syrup, taking care that the temperature does not exceed 200° Fahr. at which the urea would be decomposed. This is then saturated with alcohol, or naphtha (which answers equally well), and filtered. The solution again evaporated, almost, if not entirely, to dryness, avoiding a temperature, however, above 200° Fahr.

2. The residue so obtained, consists, for the most part, of urea or lactate of urea, with some colouring matter, some chlorides, lithates, and other salts having been separated by the former process. To this a little hot water below 200° F. is added, and the solution so obtained is completely saturated with oxalic acid. This is again evaporated at a low temperature, and set aside for a few hours. The crystalline matters so obtained consist of excess of oxalic acid, and oxalate of urea.

3. This crystalline matter is again dissolved in hot water, and precipitated by carbonate of lime: oxalate of lime is thrown down, urea and carbonic acid remaining in solution. After filtering and evaporating this solution to dryness, the carbonic acid is expelled, and crystals of urea, almost entirely deprived of colouring matter, remain behind.

This method was frequently tried, and in the following table some of the results that were obtained by this process are shown:—

2d. *Henry's method*.—1. To a given specimen of urine a saturated solution of acetate of lead is added, until no further precipitation occurs: this is filtered. In this process the phosphates and carbonates of lead are thrown down; the chlorides also, which, though soluble in water, are insoluble in saline substances. The potash, soda, &c. and the other salts, remain in solution as acetates, together with the urea, much of the colouring matter having been thrown down with the precipitates.

TABLE OF SEVENTY-TWO ANALYSES FOR UREA MADE ON SPECIMENS OF URINE VARYING FROM A SPECIFIC GRAVITY OF 1008 TO 1022.

No.	Name.	Sex.	Disease.	Diet at the time.	General character of the urine.	Sp. gr.	Gr. passed in 24 h.	Gr. of urea in 1 oz.	Gr. of urea passed in 24 h.

2. The clear solution is then re-precipitated by the cautious addition of sulphuric acid till no further precipitation occurs. It is stated that, after a second filtration, the clear solution remaining will on evaporation yield clear crystals of urea. Such is, however, not exactly true, as the sulphates of soda, potash, &c. remain in solution also, and the process is therefore apt to yield erroneous results.

3d. *Third method.*—This consisted in boiling first with animal charcoal, before proceeding with the preparation of the nitrate of urea, the object being first to get rid of the colouring matter. There is, however, one objection here,—that in this boiling a portion of the urea is apt to be decomposed.

4th. *Nitrate of urea process.*—1. The urine was prepared as in the first part of the process before described—by oxalate of lime.

2. To this residue add a sufficient quantity of dilute nitric acid to dissolve it; then place the solution so obtained in a cool place. When quite cool, add to it, drop by drop, pure strong nitric acid till no further crystallization occurs.

3. The crystals so obtained were dried and weighed, and the quantity of urea calculated from the nitrate.

This method, being the least tedious, was generally preferred.

In all, 105 specimens of urine were examined. Unfortunately, however, 33 of these were found vitiated by the absorption of moisture by some of the saucers in which they were weighed. The table here given therefore only includes 72 cases, for the most part made during the last three weeks of the competition, the other 33 being rejected as erroneous.

N.B. The numbers given at column No. 9 were obtained by analysis of different but always proportional quantities of urine. All these specimens of urine were acid, except M. O. Manners's case, No. 34; and, generally speaking, most so in the dark and turbid specimens than in the clear and pale. In No. 34 it was distinctly alkaline.

From a careful consideration of the above table it appears, that although, relatively to the quantity of urine examined, there was sometimes an excess of urea, still absolutely there was generally a deficiency, as where the specific gravity of the urine was high the quantity voided was invariably small. This remark applies to all the cases, except two—No. 52, G. Jones, and No. 54, Taylor. These, however, it is believed, are not even, after all, exceptions: in Jones's case a note of interrogation is put opposite the quantity xxij ; by the nurse's measurement only xxij had been passed. The additional number of ounces

was put down because he stated positively that he had passed xxx . besides in the closet, or thereabouts. The specific gravity of this quantity, supposing it not exaggerated, was not fairly taken,—only inferred; and, after what has already been said, no dependence can be placed on the result.

In the case of Taylor, on the day in which the xxxv of urine were saved, there had been the day before retention of urine, and about xxij of this urine were drawn by the catheter; so that, had the power of making water persisted, throughout, it is probable there would not have been so much urine passed in the 24 hours in question: part of it would have been distributed over the preceding and succeeding 24 hours.

Among the females there are no instances in which it can be clearly stated that an excess of urea occurred; perhaps because in very few was an actual measurement of the quantity of urine passed possible; but even in these cases the actual amount of urea excreted in 24 hours is probably exaggerated.

In as far, therefore, as the tables of the above cases go, it is confirmatory of Bequerel's opinion, that excess of urea is not excreted in disease in a period of 24 hours, yet it is believed that this opinion requires occasionally a modification.

1st. *A priori*, we can conceive an excess to be excreted in 24 hours in cases similar to that of Whitehead, where urea for a few days, owing to renal congestion, has not been properly excreted from the blood, giving rise at the time to the peculiar narcotic symptoms of this poison; suddenly, owing to remedial agents, the kidneys resume their functions. We believe we have seen examples of this excess in two or three cases; but, as no analysis was made at the time, the opinion cannot be confirmed by actual experiment. Extended over a period of one week, however, even in these cases there would be no excess.

2d. There are cases of excessive diuresis in which it is also probable excess of urea may be secreted in a space of 24 hours, and for several days consecutively. There was a patient some time back under Dr. Williams, Adam Plummer by name, who, on recovering from an attack of intermittent fever, and in whom the spleen was permanently enlarged, used to pass some seven pints a day of urine, and that of a specific gravity not lower than 1015, and occasionally as high as 1020. In this case, without doubt, an excess of solid matters of all kinds was excreted in the 24 hours, and it is highly probable that the urea also bore a high proportion in the quantity excreted.

3d. There are cases of cholera in which, during the convalescence, the patient may

void an unusually large quantity of urine from the same causes.

These opinions, however, rest alone on their plausibility, as we have no experiments to confirm them: indeed, as far as these go, they completely negative the question proposed.

Correspondence.

LIFE INSURANCE CERTIFICATES—SUGGESTION TO MEDICAL REFEREES.

SIR,—The subject of giving answers to the inquiries of Insurance Companies seems to me to admit of a natural division into two parts—first, what is due to my patient; and secondly, what is due to myself.

To my patient I owe the same implied secrecy on the subject of his personal health which a lawyer owes to his client on the subject of his personal affairs; and I should never think of answering any inquiries about him without his express permission.

To myself I owe the right of obtaining a reasonable remuneration for my trouble in furnishing to an Insurance Company my professional assistance, and thus enabling them to decide on the fitness of my patient as a subject for life-assurance.

I have therefore adopted the subjoined form of answer to the inquiries of insurance offices; and I shall be happy to join any gentlemen who approve of such form in having a number lithographed.

I am, sir,

Your obedient servant,
C. R. WALSH.

42, Half Moon Street, Piccadilly,
September, 1850.

SIR,—I have received the permission of _____ to answer any questions which may be put to me in confidence respecting his health for the purposes of life-insurance. I am ready, therefore, on receiving the usual fee, to place at the disposal of your office whatever information I possess on this subject.

I am, sir,

Your obedient servant,

To the Secretary of the _____
Insurance Company.

THE ROMAN HOSPITALS.

THE *Giornale di Roma* of the 19th September publishes a Papal *motu proprio*, instituting a commission of hospitals, and consolidating all the hospitals of the State into one institution, by subjecting them to uniform rules of conduct and community of interests.

Medical Intelligence.

UNIVERSITY OF LONDON.

FIRST EXAMINATION
FOR THE DEGREE OF M.B., 1850.
PASS EXAMINATION.

Monday, August 5.—Morning, 10 to 1.

Anatomy and Physiology.

Examiners, Mr. KIERNAN and Prof. SHARPEY.

1. Give an account of the cervical portion of the Vertebral column, pointing out the characters which distinguish the several parts of the bones of this region from the corresponding parts in the dorsal and lumbar regions; and describe specially the Atlas and Dentata. Enumerate the ligaments, and mention the movements which take place in this region, including those between the Cranium and the Atlas, and between the Atlas and Dentata.

2. Describe in their order of position the parts which would be brought into view in dissecting the origin and course of the phrenic and recurrent nerves on the right side of the neck. The phrenic to be traced only as far as the first rib, and the recurrent to the lower border of the larynx.

3. Give an account of the Inguinal and Femoral canals, describing their orifices, boundaries, and contents; and give the origin and course of the Epigastric Artery, the varieties in the origin and course of the Obturator, and the relations of these vessels respectively with the canals. Explain the mode of formation of Congenital, and of the other forms of Hernia which occur in this region.

4. Describe the inferior surface of the Liver, mentioning the parts with which it is in relation. Give an account of the form, situation, and structure of the Gall-bladder and ducts, and describe the vessels as far as seen outside the liver; mentioning their condition at the time of birth, and the changes which they undergo afterwards. Explain the circulation of the blood through the Liver.

5. Give an account of the Tympanum of the Ear; comprehending a description of its osseous parietes and of the parts contained in it in the recent subject.

Afternoon, 3 to 6.

1. Describe the Knee-joint, giving an account of the extremities of the bones which enter into its formation, of the cartilages, fibro-cartilages, ligaments and synovial membrane, and of the movements which take place in the joint; mentioning the muscles by which they are severally effected. Compare the knee and elbow

joints as regards their construction and movements.

2. State the dissection required to display the Musculo-spiral nerve, and its branches, from the point where it leaves the axilla to the wrist; mentioning the different parts exposed in the process, and describing their situation relatively to the nerve and to each other. The attachments of muscles not to be given.

3. Describe in their relative position the parts which would be brought into view on removing the following muscles, viz. :—

1. On the Foot—the Flexor brevis digitorum, Abductor pollicis, and Abductor minimi digiti.

2. The upper half of the Trapezius, the Splenius capitis et colli.

3. In the supra-hyoid region of the Neck—the Platysma myoides, the anterior belly of the Digastricus, and the Mylo-hyoideus.

4. Give a description of the form, relative situation, connections, and structure of the Bladder and Prostate Gland.

5. Mention the principal situations in which nervous ganglia are found. Give an account of the outward appearance and intimate structure of these bodies.

Tuesday, August 6.—Morning 10 to 1.

Chemistry.

Examiner, Professor BRANDE.

1. Give the process and theory of alcoholic etherification, and specimens of the formulæ of the several combinations of Ethyle.

2. One of the Cornish antimonial ores is a triple sulphuret of Antimony, Lead, and Copper: how would you determine the respective quantities of its four components?

3. What are the leading distinctive constituents of the urine of graminivorous, as opposed to that of carnivorous animals? Give the formulæ of those constituents, and the best modes of obtaining them in a pure state.

4. Describe the modes of preparing the compounds of Iron and of Copper contained in the London Pharmacopœia, and give their respective formulæ.

5. In Galvanic combinations rendered active by dilute sulphuric acid, and consisting respectively of Iron and Tin, Iron and Copper, Iron and Zinc, and Iron and Lead, what is the direction of the electric current, and to what practical purposes is the knowledge of that direction applicable?

Afternoon, 3 to 6.

Materia Medica and Pharmacy.

Examiner, Dr. PERKINS.

1. Give a sketch of the chemical changes

which medicines and the organism mutually suffer by their reciprocal action on each other.

2. In what do disinfectants and antiseptics differ from each other? Enumerate the chief agents used as disinfectants, and explain their *modus operandi*.

3. How is cod-liver oil obtained? By what chemical character are liver-oils distinguished from the oils of other parts of the animal body?

4. Describe the method of making and of purifying chloroform. Mention the specific gravity of this liquid; and state the tests by which its purity may be ascertained.

5. From what species of Cinchona is yellow bark obtained; and where does it chiefly grow? How is disulphate of quina manufactured? by what tests can the purity of this salt be determined? and what are the characters by which quina and cinchonin are distinguished from each other?

6. Describe the medicinal properties, uses, doses, and modes of administration of bichloride of mercury, arsenious acid, hydrocyanic acid, and iodide of iron.

7. Enumerate the chief medicinal agents which affect the movements of the iris; distinguishing those which cause dilatation, from those which produce contraction, of the pupil. And state what indications, for the use of these agents in cerebral diseases, have been drawn from their known effects on the pupil.

8. What vegetable articles of food are admissible, and what are objectionable, in a case of diabetes?

9. Describe the botanical characters and medicinal qualities of *Conium maculatum*.

Wednesday, August 7.—Morning, 10 to 12.

Botany.

Examiner, Rev. Prof. HENSHLOW.

1. Define the terms Endocarpium, Pericarpium, Papilionaceous, Diadelphus, Paracchyma, Vernatio.

2. Give such diagnoses of the following Orders as may be sufficient to include our British genera :—

Umbelliferae, Scrophularinae, Cucurbitaceae, Colchicaceae, Graminae.

3. Give such diagnoses of the following Genera as will include our British species : Hyoscyamus, Vicia, Primula, Arum, Iris. N.B. Any Candidate who may prefer describing the specimens on the table, to replying to the last questions, is at liberty to do so; confining himself to the following particulars :—

1. Leaves. Arrangement, stipulation, composition.

2. Inflorescence. General character, bracted appendages.

3. Peculiar condition of each Floral whorl; and more especially,

4. Insertion of Stamens and Corolla.
5. Reasons for referring each specimen to a particular Order.

EXAMINATION FOR HONOURS.

Thursday, August 15.—Morning, 10 to 1.

*Anatomy and Physiology.***Examiners, Mr. KIRKMAN and Prof. SHARPEY.**

Commencing the dissection at the integuments, and proceeding with it as far as the pharynx and the bones forming the zygomatic fossae, describe the parts successively exposed in dissecting the space bounded above by the zygoma, below by the base of inferior maxilla, in front by the anterior margin of the masseter, and behind by the mentus auditorius, mastoid process, and upper part of the sternocleidomastoideus.

Afternoon, 3 to 6.

1. A line being drawn round the arm two inches above, and another two inches below, the bend of the elbow, describe the soft parts seen in dissecting the included portion of the limb, both before and behind, in the order in which they appear. The joint not to be described.

2. Describe the structure and arrangement of the Mucous Membrane of the Intestines, pointing out the characters it presents in different parts of the canal.

Friday, August 16.—Morning, 10 to 1.

*Chemistry.***Examiner, Professor BRANDE.**

1. Enumerate the several combinations of *Phosphorus with Oxygen*, giving their respective formulæ, and modes of preparation. Describe the relations of *phosphoric acid* to water, and to bases, stating the distinctive characters of the several modifications of that acid and of their salts, and the best methods of determining the presence and quantity of phosphoric acid in the ordinary operations of analysis.

2. What are the substances usually found in *River and Spring water*? Give an outline of the quantitative analysis of such waters, and state the circumstances which especially influence their fitness for the supply of Towns, and for domestic use.

3. What is the nature of *Flame*, and upon what does its value depend as a source of artificial, compared with solar light? What are the several circumstances which respectively influence the *Heat* and the *Luminosity* of flame? Describe the process of *Photometry* as applicable to the determination of the relative illuminating powers of different flames.

[It is expected that detailed answers be given to the above questions.]

Afternoon, 3 to 6.

*Materia Medica and Pharmaceutical Chemistry.***Examiner, Dr. PENNIE.**

1. Give a sketch of the pharmacological history of the compounds of lead; to embrace their general chemical characteristics, medicinal and poisonous effects, therapeutic uses, and antidotal treatment; and to include a notice of the preparation and special properties of those compounds which are in ordinary use as medicines.

2. Describe the botanical character, chemical properties and medicinal and poisonous effects of the seeds of *Strychnos Nux vomica*. State how strychnia is obtained, and describe the chemical characteristic of this alkaloid as well as of brucia. Lastly, mention the physical and chemical characters by which cusparia bark is distinguished from the bark of the *Strychnos Nux vomica*.

3. Describe the modes of preparing the compounds of ammonia contained in the London Pharmacopœia; and give the theories of the processes and the formulæ of the various compounds.

4. You are required to state by what characters you would detect—

a. The adulteration of scammony with chalk, starch, and guaiacum.

β. The substitution of carbonate of zinc for the oxide of that metal.

γ. The presence of the leaves of *Cyanacum Arget* and of *Tephrosia apollinea* in Alexandria senna.

δ. The intermixture of the meal of white mustard seeds with that of black mustard seeds.

e. The presence of nitrate of potash in commercial nitrate of silver.

ζ. The contamination of chlorate of potash with chloride of potassium.

η. The adulteration of powdered rhubarb with turmeric.

θ. The presence of sulphate of lime in *Hydrargyri Ammonio-chloridum*, Ph. Lond.

5. Enumerate and classify alimentary principles; give their chemical formulæ; and state the uses which they respectively serve in the animal economy.

6. Name the substances respectively marked A and B.

N.B. *The use of a Microscope will be supplied to those who desire to avail themselves of its aid in answering the last question.*

Saturday, August 17.—Morning, 10 to 1.

*Botany.***Examiner, Rev. Prof. HENBLOW.**

1. Define the terms *Carpella*, *Commisura*, *Raphe*, *Distichus*, *Thyrus*.
2. Confine your descriptions of the spe-

cimens on the table, by giving specific answers to such of the following particulars as they may be suited to exemplify:—

- a. STEM. General character.
- b. LEAVES. Arrangement.
- c. ——— Stipulation.
- d. ——— Composition.
- e. ——— Form.
- f. ——— Margin and Incision.
- g. ——— Venation.
- h. INFLORESCENCE. General Character.
- i. ——— Bracteal appendages.
- j. FLOWER. Peculiarities of Calyx.
- k. ——— Corolla.
- l. ——— Stamens (as to insertion, &c.)
- m. ——— Disk.
- n. ——— Pistil (as to Ovary, Style, Stigma, Placentation.)
- o. FRUIT. General Character.
- p. ——— Dehiscence.
- q. ——— Placentation.
- r. ——— Arrangement of Seed.
- s. SEED. Reasons for considering the Embryo to be Monocotyledonous or Dicotyledonous, if it should not be present or happens to be indistinct in the specimen under examination.

- f. PLANT. Reasons for referring it to a particular natural group (Order or Genus) to which it may belong or nearly approaches.

3. What are the chief adventitious inorganic constituents found in plants, naming a few examples in which one or other of them are peculiarly abundant?

4. What are the conditions essential to the germination of seeds?

5. State some of the most remarkable phenomena attributed to the peculiar irritability manifested in some plants.

ABOLITION OF INTRAMURAL INTERMENTS. —THE WALKER TESTIMONIAL FUND.

A HIGHLY respectable body of gentlemen have associated themselves for the purpose of raising a public subscription as a reward to Mr. G. A. Walker for the services he has rendered to the cause of sanitary reform, in promoting the abolition of interments in the metropolitan graveyards. We extract the following paragraph from the report recently issued by the Committee:—

"It has been justly remarked, that 'of all the great undertakings by which the era is signalized, there is none, perhaps, which so clearly stamps a character of real and essential progress as the sanitary movement; for the result of this, mediate and immediate, is a positive, a cumulative good,—a social, moral, and intellectual amelioration of a most beneficial nature, one which is destined to effect great issues in the material advancement of the people at large.'

But this reform, as regards intramural sepulture, will be attended likewise by great economic gains. By the showing of the Board of Health on this subject, the Metropolis alone will benefit by an improved system of burial without the walls to the extent yearly of *three hundred and fifty thousand pounds*; and taking into view also the savings contingent upon the adoption of this better system throughout the cities and towns of the United Kingdom, it is not unreasonable to anticipate that an aggregate annual saving will arise of at least two millions. Can, then, the householders of London, and the kingdom generally, fail to recognise and reward the man whose claim to their gratitude stands lower upon this score, than upon those other and higher considerations which have been already enumerated? We have recently seen the munificent testimonial which has rewarded the successful exertions of a fellow-labourer with that League whose united efforts repealed the corn laws. The Committee point to the £74,000 Cobden Testimonial Fund. Let it not be said that the single-handed champion, whose indomitable spirit, in the face of prejudice, corruption, and error, has overthrown the crying abomination of burying the dead among the hearth-seats of the living, will want a league of contributors to his Testimonial Fund. Let it not be said that a lesser meed of thanks is owing to the man whose incessant labours have secured to us immunity from poison and death in the air we breathe, than to him who has thrown open the gate to toiling and willing industry, or that life and death are of less intrinsic value than the means of existing prosperously. Pure air is more necessary in crowded cities than even a free supply of food, as doubtlessly the returns of the Registrar-General will ere long, now that this nuisance is abolished, sufficiently prove. Henceforth every year in London sixty thousand fresh corpses will cease to give off many thousand times the bulk of their own bodies in the corruption of the atmosphere. We give testimonials to the brave soldier, the gallant sailor: let us not be behind-hand in rendering the tribute of justice to the meritorious citizen who has applied his knowledge of the science of medicine to the acquisition of a peaceful victory over the united powers of ignorance, superstition, self-interest, and prejudice."

* * * We regret to find that the Government has declined making any remuneration to Mr. Walker for the important services which he has rendered to the public. We trust the Committee may meet with that success which such a laudable undertaking deserves.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN IN LONDON AND ITS VICINITY.

THIS Society was formed in the year 1788, with the object of establishing a fund for the relief of those widows and orphans of deceased members who might need and be deserving of assistance.

It unites the advantages of a Provident with those of a Benevolent Society. It is provident, as the members may through it protect their families from destitution; and it is benevolent, as its benefits are conferred on those who are left in indigent circumstances. All duly qualified members of the profession residing within the limits of the Society are eligible for proposal, and the mode of admission is by ballot.

The Society's affairs are managed by a President, twelve Vice-Presidents, three Treasurers, and twenty-four Directors, who are elected by the members annually, and whose services are gratuitous.

The Society has been greatly assisted by legacies and contributions from members and others, and has especially to acknowledge the gracious patronage of various members of the Royal Family.

The permanent efficiency of the Society depends on the maintenance of a due proportion between the available income and the claims made on the funds. Computations have been made by experienced actuaries on all points susceptible of calculation by way of average.

The proportion of members whose families may become claimants for relief scarcely admits of calculation; but the experience of more than fifty years has proved the wisdom and benevolence with which the Society was planned, and the prudence and efficiency with which its affairs have been conducted.

The Society is enrolled among Friendly Societies. The capital stock, converted into sterling money, is invested in the Bank of England at compound interest, and amounts to more than £45,000.

80 widows and 37 children have been relieved since 1792. 31 widows and 20 children are now receiving relief, which amounts to more than £1,400 per annum.

Laws, lists, and forms of proposal, may be obtained from the Secretary, and will be sent by post on receipt of two stamps.

C. E. WALSH, Secretary.

43, Half Moon Street.

THE HAHNEMANN HOSPITAL AND ITS SUPPORTERS.

At a general meeting of the Board of Management held at the Hospital, 39, Bloomsbury Square, on Saturday last, the following gentlemen were elected medical

officers:—Jas. Chapman, Esq., M.A., Cantab., and M.D.; E. C. Chepmell, Esq., M.D.; P. F. Curie, Esq., M.D., Paris and Aberdeen; R. E. Dugeon, Esq., M.D.; Thos. Engall, Esq., M.R.C.S.; Jos. Hands, Esq., M.R.C.S.; A. Henriques, Esq., B.L., M.R.C.S.; H. Kelsall, Esq., M.D., F.R.C.S.; H. V. Malan, Esq., M.D.; M. Roth, Esq., M.D.; D. Wilson, Esq., M.R.C.S. The Hospital, which has for its President that amiable nobleman, Lord Robert Grosvenor, is to be opened for the reception of patients on the 16th of October.

If we record this event, it is to express our regret that M.D.s, F.R.C.S.s, and M.R.C.S.s, are to be found lending their support to principles of treatment which are based on dogmatic assumption, or on the most palpable absurdities connected with the alleged action of medicines. It is highly creditable to the Apothecaries' Society that not one of their licentiates is to be found in this list. When men who must have received a regular medical education thus put themselves forward as supporters of a gross delusion, the public mind is likely to be unsettled regarding the teaching and practice of medicine in our schools and colleges. If Hahnemann's principles be *bonâ fide* carried out in the new Hospital in cases of acute disease, we predict that the emoluments of the coroner for Middlesex will be very considerably increased.

THE CHOLERA AT MALTA.

LETTERS from Malta of the 22d September announce the death of Surgeon Thompson, of the 69th Regiment. The non-commissioned officers and men have requested permission to subscribe three days' pay for the erection of a monument to him. The cholera had sensibly abated in Malta as to the number of persons attacked, but its power on those attacked is not diminished, death but rarely following within eight hours.

ON THE PER-CENTAGE OF NITROGEN AS AN INDEX TO THE NUTRITIVE VALUE OF FOOD. BY DR. A. VOELCKER.

THE object of this paper was to show that the usual estimation of the nutritive qualities of an article of food is frequently attended with inaccuracies, which renders it desirable to modify our present methods in this respect in many cases. A circumstance which leads to considerable error is the presence of ammoniacal salts in the juices of plants. In order to prove experimentally the presence of ammoniacal salts in larger quantities than hitherto suspected, and to avoid the objection that they might result from a partial decomposition of albuminous substances during the

analysis, the author chose fungi for his experiments, which are rich in nitrogen, and known as being highly nutritious. The species used was *Agaricus premellus*, a species which is edible, and remarkable for forming most beautiful fairy rings. After having separated all soluble protein compounds by means of basic acetate of lead, which re-agent throws down these completely, the amount of nitrogen still present in the juice of these agarics in the form of ammoniacal salts was found to be 0.204 per cent. for the fresh fungi, or 1.68 per cent. for the dry fungi. The whole amount of nitrogen in the same agarics, collected at the same time, determined by combustion, was found to be 0.74 per cent. for the fresh fungi, or 6.61 per cent. for the fungi dried at 212° F. Deducting from the last stated numbers the quantity of nitrogen found to exist in the juice in the form of ammonia, we find that only 0.586 per cent. of nitrogen in the fresh, or 4.799 per cent. of nitrogen in the dry fungi, exists in the state of protein compounds, and that nearly one-third of the nitrogen obtained by direct combustion exists in the form of ammonia in the juice, or, at all events, in the form in which the nitrogen adds nothing to the nutritive value of the fungi. The nutritive value of fungi has thus been overrated considerably; and there can be little doubt that the same is the case with many vegetables, which, according to the author's experiments, contain sometimes considerable quantities of ammonia in the form of ammoniacal salts.

Dr. CHRISTISTON remarked that he had long been convinced that there was a considerable fallacy in the methods of determining the value of nitrogen, and he hoped Dr. Voelcker's communication would direct inquiry in a more satisfactory direction.—*British Association*, 1880.

ON THE REMOVAL OF THE INCrustATION WHICH FORMS IN THE BOILERS OF STEAM ENGINES.

At the recent meeting of the British Association at Edinburgh, a paper by Dr. G. Wilson, On the Incrustation of Boilers, was read by Dr. Davy. Dr. Wilson observes—"Considering the composition of the incrusting matter, and the properties of its principal ingredient, the sulphate of lime—a compound soluble in water and in sea water, and deposited only when the water containing it is concentrated to a certain degree—there appears to be no difficulty theoretically in naming a preventive. The certain preventive would be the substitution of distilled or rain water in the boiler for sea water. Of this we have proof in the efficacy of Hall's condenser, which returns the water used as

steam, condensed, after having been so used; but, unfortunately for its practical success, the apparatus is described as being too complicated and expensive for common adoption. Further proof is afforded in the fact that the boilers of steamers navigating lakes and rivers in the waters of which there is little or no sulphate of lime, month after month in continued use, remain free from incrustation. This I am assured is the case with the steamers that have been plying several summers successively on the lake of Windermere. And it may be inferred, that in sea-going steamers in which sea water is used in the boiler—or, indeed, any water containing sulphate of lime—the prevention of deposition may be effected with no less certainty by keeping the water at that degree of dilution at which the sulphate of lime is not separated from the water in which dissolved. From the few trials I have made, I may remark that sulphate of lime appears to be hardly less soluble, if at all less, in water saturated with common salt than in perfectly fresh water. This seems to be a fortunate circumstance in relation to the inquiry as to the means of prevention, and likely to simplify the problem. If these principles be sound, their application under different circumstances, with knowledge and judgment on the part of the directing engineer, will probably not be difficult. His great object will be, in sea-going steamers, to economize the escape of water in the form of steam, and thereby also economize heat and fuel; also, when fresh water is available, to use it as much as possible; and further, to avoid using sea water as much as possible near coasts, and in parts of seas where sulphate of lime is most abundant. From the incrustation on the boilers of sea-going steamers, the attention can hardly fail to be directed to that which often forms, to their no small detriment, in the boilers of locomotive railway engines, and of engines employed in mines and in the multifarious works to which steam power is now applied. These incrustations will of necessity be very variable, both in quantity and quality, according to the kind of ingredients held in solution in the water used for generating the steam. Hitherto I have examined two specimens only of incrustations taken from the boilers of locomotive engines, and a single one only from the boiler of a steam engine employed on a mine—a mine in the west of Cornwall. The latter was fibrous, about half an inch thick, and consisted chiefly of sulphate of lime, with a little silica and peroxide of iron, and a trace of fluorine. The former were from one-tenth of an inch in thickness to one inch. They were laminated, of a grey colour, and had much the appearance

of volcanic tufa: they consisted principally of carbonate and sulphate of lime, with a little magnesia, protoxide of iron, silica, and carbonaceous matter—the last two, the silica and carbonaceous matter, probably chiefly derived from the smoke of the engine and the dust in the air. From the engineer's report it would appear that the thinnest—the incrustation of about one-tenth of an inch—had formed in about a week, during which time the locomotive had run about 486 miles, and consumed about 10,000 gallons of water.

OBITUARY.

On the 17th of July, at 7, Allason Terrace, Kensington, of apoplexy, Mr. Francis Morgan Walker, surgeon, late of Chesterfield, Derbyshire.

On the 15th of April last, at Hobart Town, Van Diemen's Land, Thomas Gibson, Esq., Donno, Scotland, surgeon, R.N.

On September 12th, at Carlou, Launceston, Armstrong, Esq. M.D. late of Dublin.

Of small-pox, Joseph Robinson, M.D., of Omagh.

Selections from Journals.

ON THE EPIDEMIC CEREBRO-SPINAL MENINGITIS OBSERVED AT VAL-DE-GRACE, 1848, 1849. BY DR. MICHEL LEVY. CHIEF PHYSICIAN.

THIS epidemic has manifested so fatal a predilection for the French Army, that there is scarcely one important garrison that has not suffered from its ravages. Paris, which had before escaped, has become the seat of its influence during the last sixteen months.

The first case appeared in the Military Hospital at Val-de-Grâce in Dec. 1847: from this date to Feb. 1849, a period of fifteen months, ninety-nine cases were presented.

The following table indicates the progress of the disease, and the rate of mortality:—

1847. Dec.	1 Case.	1 Death.
1848. 1st. q.	12	6
" 2nd "	26	12
" 3rd "	12	5
" 4th "	23	12
1849. Jan.	11	9
" Feb.	14	12

Dr. Levy then refers to the epidemic constitution of the previous year in relation to the prevalence of this cerebro-spinal meningitis.

From the statistics of the cases admitted into Val-de-Grâce, it appears that, of six thousand four hundred and ninety-eight patients received from Jan. to Dec. 31st, 1849, there were only ninety-eight cases of meningitis; that during the third quarter, when the number of admissions was at its maximum, there were only twelve cases of

meningitis; that not only did the ordinary pathological features of the year manifest themselves in the increase of the affection of the respiratory and digestive organs during the winter months, but that other epidemics of greater intensity prevailed simultaneously; such as typhus fever, dysentery, variola, measles, and scarlatina. The meningitis now under consideration cannot, therefore, be regarded as a true epidemic, because it has neither attacked a large number of individuals, nor are its attacks limited to a restricted period; neither have they modified the characters of other epidemic diseases. It has been known occasionally at Val-de-Grâce for many years, but has increased in frequency since the close of 1847, and has not prevailed in other hospitals. The constitution of 1848 was seen in the tendency to miasmatic and infectious diseases marked by a typhoid and adynamic character. Dr. Levy assigns the origin of the diseases of this year to a prevalent morbid condition of the blood.

It must be observed that this meningitis appeared between, and was to a certain extent merged in or complicated with, the influenza of 1847, and the cholera of 1849.

Mortality.—Of the ninety-nine cases received into the Val-de-Grâce, fifty-eight died; a proportion of 1 in 170. The mortality greatly declined towards the close of 1848, but rose again greatly in Jan. and Feb. 1849.

Of fifty-three deaths, thirty-eight occurred between the ages of seventeen and twenty-five years; and only fifteen between those of twenty-five and thirty-one years. The young men recently incorporated with their regiments furnished the greater portion of the fatal cases. This may in part be attributable to the excitement of novel duties, exercises, &c.; and in part to the irregularities and political excitement of their preceding life.

Precursory symptoms.—In twelve cases out of fifty-seven the attack was sudden, but in general the following precursory symptoms were observed: headache, vertigo, lassitude, horripilations, tremors, general malaise, nausea and vomiting.

Symptoms.—In most cases there was intense and intolerable frontal headache. Pain in the course of the spine, for the most part in the lumbar region, was produced by movement or the slightest pressure, and in some instances existed without being so excited. Pains in the limbs were constant symptoms. Rigors occurred during the convalescent stage, or when the disease was verging into a chronic state. At this period, a state of torpor, or general languor and debility, somewhat analogous to a certain stage of cholera, would frequently supervene. Impairment of the senses of sight and

hearing not unfrequently remained after the attack. Rigidity of the spinal muscles of the cervical and dorsal regions existed in the majority of instances. Trismus, opisthotonos, pleuristhotonos, strabismus, contraction of the limbs, and tetanic spasms, were occasionally met with. In some instances delirium accompanied the early symptoms, and was followed by coma. Vomiting was a frequent symptom: constipation was constantly observed, and extremely difficult to overcome. The tongue was generally normal at first, then becoming whitish passed through several shades till it presented a typhoid aspect. In twenty-six cases a peculiar pearly appearance of the gums was noticed. Anorexia was constant. The pulse throughout the disease was hard and sharp, and varied in number from 60 to 120, in individual cases. The face in many cases was florid. The blood in most instances was cupped, when drawn at the commencement of the disease, and generally exhibited an excess of fibrine. Respiration was hurried; the forehead hot, the surface of the trunk was warm, the extremities cold. During return to health it was not easy to maintain the warmth of the body. In twenty-eight cases various cutaneous eruptions, *e. g.* erythema, erysipelas, petechiae, sudamina, herpes, rubecloid spots, &c. were met with.

The complications were for the most part of a typhoid or choleraic character.

Course of the disease.—Distinct stages were not observed. The disease was usually ushered in by smart febrile symptoms accompanied with delirium, in some cases alternately with coma. The cases varied according to the predominance of any certain set of symptoms. The nearest division that could be made was that of complete and incomplete meningitis. In some cases only headache, cervical rigidity, vomiting, and constipation, were observed until febrile reaction changed or developed the full characters. In other cases the entire characteristic symptoms were rapidly developed. The epithet "typhoid" was applied to those cases in which a state of torpor analogous to the collapse of cholera occurred.

For all practical purposes the epidemic meningitis may be divided into the three forms of congestive, purulent, and hydrocephalic; the first form being that of the sudden seizures and rapid cures occasionally met with. Under either form, when the course of the disease was prolonged, it manifested remissions in the symptoms, and even a periodicity giving an intermittent character.

The course of the disease seemed in some cases to be cut short by an increased discharge of urine. The urine did not contain

albumen, but a considerable quantity of uric acid and urates was noticed when the critical discharge occurred. In a few cases profuse perspiration preceded a favourable termination. Haemorrhage and diarrhoea exerted no favourable influence on the course of the disease.

The duration of the disease varied from eight to sixty days.

In ten cases, the period of the disease was from thirty to a hundred and fifty-one days, convalescence having been interrupted by pleurisy in one case, by obstinate headache, irregular or periodic, in four cases, twice by typhoid symptoms, once by deafness, and twice by persistent vomiting.

Pathological anatomy.—Dr. Levy's observations under this head are deduced from forty-four autopsies.

In fifteen there were noticed fulness of the vessels, injection of the pia mater, and sanguineous extravasation within the arachnoid.

In nine cases there was a marked abundance of bloody points in the out cerebral surface.

In five, injection of the ventricular surfaces.

In twenty-seven, purulent effusion on the convexity and at the base of the brain.

In twenty-seven, purulent effusion, situated almost exclusively on the posterior surface of the spinal cord; eight times on both anterior and posterior aspect, and four times it extended to the *cauda equina*.

In eighteen cases there was effusion of serum and lymph into the cavities of the ventricles.

In eleven instances thoracic disease was found: viz. two, pneumonia; nine, pulmonary congestion; one, sero-purulent effusion into the pericardium.

In the latter case inflammation of the joints co-existed.

Treatment and results.—Of sixty cases noted, thirty-one deaths occurred from the natural course of the disease; seven from hydrocephalic disease; twelve were completely cured; and ten incompletely cured.

The means generally employed were venesection, leeching, cupping, blistering, and calomel.

Conclusions.—1. The cerebro-spinal meningitis which has presented itself at Val-de-Grâce during 1848-49, is identical with that which has been observed at Versailles, Strasbourg, Metz, &c.

2. It has prevailed concurrently with typhoid fever, but is otherwise distinct in its symptoms, course, lesions, and mortality.

3. It has not assumed a true epidemic character; at the time that it has prevailed, typhoid and other eruptive fevers have been met with in considerable numbers.

4. It has not been developed under the miasmatic conditions which give rise to periodic fevers.

5. With the exception of one or two cases of sudden seizure, the pathological lesions have generally borne a close relation to the symptoms, which they have thrown light upon; and this is not a feature in typhoid disease.

6. The rapid and extensive formation of pus is amongst its most constant and remarkable lesions.

7. The tendency to the formation of pus is the generic feature of a class of affections in which the blood becomes diseased, and is also a part of this cephalo-rachidian meningitis. The special tendency to the deposition of pus in the cerebro-spinal axis constitutes its specific character.

8. The medical constitution of 1847-48 explains the prevalence of this class of diseases.

9. By the demonstration of the non-identity of this cerebro-spinal meningitis with typhus, its non-identity with typhoid fever is also demonstrated.—*Gazette Médicale*.

. An epidemic of a similar character to the above has been noticed by Dr. Duncan of Dublin, and of which mention will be found in our review of Dr. Duncan's Clinical Lectures, at p. 552 of our 44th volume.

PROCESS FOR THE QUANTITATIVE EXAMINATION OF OPIUM, AND SEPARATION OF MORPHIA. BY M. GUILLEMOND. LYON.

TAKE 15 grammes (=8·8 Eng. drachms) of the opium to be examined; and, having cut it into small pieces, mix it in a mortar with 60 grammes (=15·4 Eng. drachms) of alcohol, at 180° Fahr. This mixture is to be filtered through fine linen, and the dregs to be treated again with 40 grammes (=10·3 Eng. drachms) of alcohol, at the same temperature as before. The two tinctures are to be mixed in a large wide-mouthed flask, 4 grammes (=1·028 Eng. drachms) of Liq. Ammoniac being added. The result of the process is obtained in twelve hours. The morphia will be separated, and found lining the sides of the vessel in tolerably large, coloured crystals, of a gravelly feel. Mixed with these in a small proportion are the pearly, needle-like crystals of narcotine. These crystals thus mixed are to be placed on linen, and washed several times with water, to remove any portion of meconate of ammonia which may be adherent to them. The crystals are then to be collected, and placed in a tube full of water. The narcotine, which is very light, will remain suspended in the water, while the heavier morphia will be de-

posited, allowing the narcotine to be separated by decantation. The quantity of morphia in any given specimen of opium can thus be ascertained by the weight of the deposit. Good opium should yield a proportion of $1\frac{1}{4}$ to $1\frac{1}{2}$ of crystals of morphia to 15 of the solid opium—i. e., about ten per cent.

M. Miahle has found the preceding mode of analysis succeed to his satisfaction; but he proposes as an improvement, that, having dried the mixed crystals, they should be triturated in a small quantity of ether, whereby the narcotine will be more readily and more completely separated from the morphia.

M. Miahle states also, that by the employment of this process in the examination of various specimens of opium he has confirmed the statement of Vauquelin and Dublanc, that indigenous opium contains a larger proportion of narcotine than of morphia, and is therefore not adapted for therapeutic purposes.

M. Miahle further states that he has found as great differences in various specimens of official opium as from a half to ten grammes of morphia in 100: so necessary is it that the examination of the drug should precede its employment. To constitute good opium, the proportion of morphia should be from six to nine per cent., or, as a mean, $7\frac{1}{2}$ per cent.—*L'Union Médicale*. X

ON GLAIRINE, GLAIRIDINE, AND ZO-IODINE IN MINERAL WATERS. BY M. BONJEAN.

THE gelatinous matter frequently met with in mineral waters was regarded by Borden as sometimes a fatty matter, and sometimes as of a bituminous nature. Vauquelin stated that it was analogous to albumen.

Different names had been given to this substance, by various authors, taken from the characters of the waters in which it had been met with. Anglada has recognised the identity of all these varieties, and has named the substance *glairine* from its glairy aspect.

M. Bonjean has discovered a variety which he designates *glairidine*; and has also discovered another product of a violet colour, which he denominates zo-iodine.

M. Duby, an eminent Genevese botanist, has examined the substance at the request of M. Bonjean, and declares it to be an extremely delicate plant of the finest texture, and so folded on itself as to have the appearance of animal detritus.

M. Bonjean gives the following results of his investigations into the nature of *glairine*:—

1. It contains very little nitrogen.
2. It contains no iodine.
3. It is slightly soluble in water, alcohol,

and spirits of turpentine; more so in the concentrated acids, whence it is again precipitated by alkalis in the form of bluish flocculi. Heat, in all cases, favours its solution.

4. It is entirely insoluble in ether.

5. When separated from a mineral water it rapidly becomes of a greyish colour; but in contact with nitric or hydrochloric acids, chloride or bromine, it immediately regains its white colour.

6. Strong alkalis change its colour to green.

7. It is inodorous in water. Separated from that fluid it acquires a repulsive odour.

8. By drying it loses its odour, and at the same time is reduced to one-tenth its previous weight.

9. Hydrochloric acid separates a portion of iron. Iodine gives it a brick-red colour. *Glairidine* differs but little from *glairine*. Its colour is naturally grey; it emits no odour. Acids and alkalis do not change its colour as they do that of *glairine*: it contains traces of iodine.

When *glairine* is separated from its mineral water, the water which passes through the filter is at first nearly colourless, and at the end of two or three hours deposits spangles of a beautiful violet colour, and strongly iridescent. These are the new substance *zo-iodine*, inodorous, insipid, insoluble in water, permanent in the air, reddened by acids, and made brown by alkalis; when burnt yielding the odour of burnt horn.

M. Bonjean has also detected *glairine* in some earths and minerals.—*Journal de Chimie Médicale*. X

NOTICES TO CORRESPONDENTS.

The communication of Mr. E. W. Roberts will be inserted.
The pamphlet forwarded by Dr. Kennedy to receive our attention.
Dr. F. Steel's letter and enclosure have come to hand. The subject shall be noticed in a future page.
Mr. H. C. Johnson.—The Address will be inserted and the request of our correspondents complied with.

Lecturers.

INTRODUCTORY REMARKS

to

*The Opening of the Session 1850-51, at
St. George's Hospital.*

BY HENRY CHARLES JOHNSON, ESQ.
Assistant-Surgeon to the Hospital, &c.

SIR,—I could have wished that one of the officers of this establishment more competent than myself had been selected for the purpose of opening the proceedings of this day. Most sensible am I that my powers are inadequate to do full justice to the subjects I have to submit to your consideration.

Since the existence of a school connected with this hospital, it has been the custom of the lecturers, at the commencement of each winter session, to address to those gentlemen who honour them by their presence, some introductory remarks, either on the general conduct of the school, or on matters connected with the plan of education to be pursued by those about to enter upon their professional career.

Of the utility or expediency of such annual addresses many opinions prevail; but custom has hitherto held its sway, and no school in this metropolis considers that it has fulfilled its duties, or the expectations of its supporters, without its annual introductory lecture.

My colleagues, however, have deemed it advisable to discontinue this practice, and to open the present session by distributing to the meritorious students of this school, those rewards and distinctions which they have gained by their industry and talents. They have considered that it would be more gratifying to this meeting, and more especially to those who have received their education at this hospital, to witness the success attendant on the efforts of some of the junior members of our profession, rather than listen to the dry and uninteresting detail of an ordinary introductory lecture. They felt, moreover, that a wholesome stimulus would be given to the exertions of those about to commence their studies, to gain by their efforts similar rewards and distinctions, to those which will be conferred this day on the most deserving students of preceding years.

Before I present to you the successful candidates for the various prizes offered in this school, I may perhaps be allowed to make a few remarks on the institution

which these gentlemen have adopted as their alma mater, and point out to them the distinguished position they may attain, if they do but follow in the track of many of their predecessors, who, with much fewer opportunities than those which they possess, attained a fame and eminence in their profession to which I would have them aspire.

It is little more than a century ago that St. George's Hospital reared its head from being a small infirmary, in Petty France, in Westminster, and subsequently in Chapel Street, to the rank and standing of a metropolitan hospital. In 1733, the subscribers finding that their patients increased, and that a corresponding improvement took place in their funds, exerted themselves to find a house in a more airy and convenient situation, and at length procured a lease of Lanesborough House, at Hyde Park Corner, at an annual rent of £80, as being, on account of the largeness and strength of the building, and airiness of the situation, most convenient for the purposes of the charity. The improvement in the funds soon afterwards enabled the governors of the institution to extend their benevolent views, and for that purpose to purchase, of the Dean and Chapter of Westminster, the freehold of the ground whereon the hospital now stands, in order to settle the charity on a permanent foundation. For a century Lanesborough House remained much in its original form; it was then raised to the ground, and the present splendid edifice in which we are now assembled, was, by the munificence of the governors and the liberality of the charitable public, erected in its place. Upon the incalculable benefits thus bestowed on the sick poor I need not dwell on the present occasion; they are echoed through the homes of the afflicted and the destitute.

From the foundation of this hospital, not only have the sick and lame received aid, comfort, and skill, in the alleviation and cure of their diseases, but the practice, the science, and the literature of our profession have been enriched by the labours of those who have gleaned their information within its wards.

In the early part and towards the middle of the last century, William Hunter flourished, and enriched our knowledge on many important subjects connected with anatomy, surgery, and midwifery. From him we learned the uses of the absorbent system. To him we are indebted for some interesting pathological facts connected with the joints, the discovery of the tubuli testis, of the ducts of the lachrymal gland, and other useful researches in anatomy and medicine too numerous to mention on the present occasion. His splendid ma-

scum, and his work on the Gravid Uterus, place him in the foremost ranks of the eminent of our profession. His life and persevering zeal may be considered as a model for future men to emulate and to admire. He, sir, was a pupil of this hospital!

After his time a long succession of illustrious names adorn the annals of St. George's. John Hunter soon followed his brother William; and in this institution did he collect those facts and materials from which, by his acumen and powers of classification and arrangement, he deduced those great principles which, I may justly say, have proved the beacon and the guide in the treatment of disease, to the admiring and enlightened countries of the world.

Nor, sir, do we cease with the fame of the Hunters. It was here that Cheselden operated for the stone, which was considered in his time, and justly so, as an operation of danger and difficulty. A curious resolution stands on the books of our hospital about this period, which says:—

"That the cutting for the stone be left to such surgeons as think proper to perform the same." The mode of operating, and the instruments wherewith it was performed, although determined by Cheselden, were improved by Sir Caesar Hawkins; and the gorget which he here employed still remains in use amongst many of our best surgeons of the present day.

Towards the conclusion of the last century and the commencement of this, we find the followers of John Hunter securing and extending their reputation by his precepts and his example. Sir Everard Home may be said to be the pupil of John Hunter, and from him gleaned many of the materials for producing his magnificent work on Comparative Anatomy, which must ever remain a monument of his industry and his fame.

Nor, sir, is it fitting in me to hold up alone for imitation the great surgeons who have adorned this institution.

By one of the physicians of this hospital was that stimulus and zest given to the study and cultivation of morbid anatomy, which has raised to the level of the higher sciences the practice of our profession. Till the time of Baillie, morbid anatomy, the most important of all investigations in the knowledge and treatment of disease, was to a certain extent neglected in the schools. From his time, however, pathological inquiry has been carried on with an energy and success which has spread from hence to all the great capitals of Europe where facilities are afforded for its culture and pursuit. To morbid or pathological anatomy must we look for the abolition of empiricism, and to more per-

fect and surer methods of relieving human suffering.

Drs. Pemberton and Heberden, sir, afford us examples, in the strict and lucid manner in which they portrayed disease, in their forcible and elegant dissertations on some of the most interesting and important points in the practice of medicine; and Dr. Hope, more recently amongst us, may be said to have contributed largely to our information respecting the diseases to which the heart and circulation are prone.

Nor, sir, has general science failed to gather its triumphs from those who have gone before in their useful career at the bedside of the patients of this charity. The names of Young and Wollaston enrich the catalogue of our predecessors. The former brought to bear all those great truths with which natural philosophy furnished him, upon his efforts to alleviate the miseries of those submitted to his care. True philosophy and the profoundest learning marked the character of the late Dr. Young.

The latter, Dr. Wollaston, was pre-eminent for his chemical knowledge and research; and though he failed in obtaining his wish to become an officer of this establishment, yet we enjoy the merit of ranking him amongst the most renowned and popular of those who have studied in this school.

If, sir, we consider the advantages which are enjoyed by the sick poor, and by the profession to which we belong, from the existence of public hospitals, we shall find that they weigh but light in the scale against the real and substantial good which accrues to the country at large, and its numerous dependencies abroad, through the medium of the schools of medicine which are everywhere connected with them.

This hospital in its earlier days laboured under the disadvantage of possessing no real property on which to found its basis. Its very existence depended on its good name, and on the charitable wishes and benevolent views of its original founders and supporters. A delicacy (and though a mistaken a very natural one) prevailed lest the feelings of those who were unfortunately the subjects of disease might be intruded upon and offended by extending the knowledge of their sufferings beyond the observation of their actual medical attendants.

But happily, sir, for society at large, these highly to be commended, but mistaken notions, no longer exist, and in our present more extended views and ideas on the dissemination of knowledge, a school of medicine is considered as much an integral part of a public hospital, as any other adjunct which may be employed for

the benefit of the sick poor who come within its walls.

Sir, so fully has this become a general rule and principle, that in some establishments devoted to learning and education, a school of medicine has been formed long before those institutions possessed efficient hospitals of their own to illustrate the precepts which they taught, the school being considered as the surest foundation on which to raise the superstructure of their future asylums for the sick and needy.

The necessity of teaching, and consequently of a school of medicine connected with St. George's Hospital, was determined by a resolution of the governors as far back as the year 1793. Amongst other regulations, the following appears:—

"That an operation be performed on a dead body, attended by explanations, or a lecture given on some of the principal parts of surgery, once a week, by one of the surgeons of the hospital in rotation, for nine months in the year."

Here, sir, do the governors enforce on us the necessity of teaching. From that time to the present has a school of medicine gradually developed itself, and, as it now exists, may vie with the oldest and most wealthy of this metropolis, affording as it does every facility for the successful study of disease.

The school, moreover, has received the fostering care of the governors at large, who by their liberality have lately supplied us with suitable accommodation for teaching anatomy and chemistry, in premises set apart from the hospital itself. These, together with the other appurtenances of lecture-rooms and museums within this building, have placed the necessities of the school in a most efficient form.

While the Governors have thus offered inducement to the students of this hospital for the successful cultivation of medical science and pursuits, the teachers have not been backward in holding out rewards to industry, talent, and good conduct. Scholarships and prizes have been instituted as premia to knowledge and exertion. Nor, sir, have others, at one time connected with this hospital, and who feel that an impetus should be given to medical education and aspiring talent, been wanting in their generous efforts to promote the welfare of the School. Your own name, sir, and that of Dr. Chambers, stand on the list to-day as bestowing prizes on the subjects of clinical medicine and clinical surgery.

In selecting, sir, as I have done, a few of the most remarkable individuals to whose lives and labours I would direct the junior part of my auditory, I would have them bear in mind that we have yet amongst us those whom they would do well to imitate,

as examples of professional zeal and professional success,—those who have contributed by their works to establish principles in the treatment of disease, which will long outlive their worldly career, and secure a lasting reputation for themselves, and for the school in which they have taught and laboured.

In the present remarks I have offered no novelties to attract your attention. I considered that a brief sketch of the origin and progress of this splendid charity, which may well be ranked amongst the best and proudest of this great city, might not be altogether uninteresting to some of my auditory; and that to the junior part I might point out the paths which are now open for the exercise of their talents and industry, that they may be led to zeal and emulation by the example of those ornaments of our profession, who have toiled in the same field they are about to occupy, and to stimulate them to advance, by their instrumentality, the good intentions of the supporters of this hospital, in promoting the advancement of science, and the amelioration of the sufferings of their fellow-creatures.

In conclusion, I must congratulate these gentlemen in receiving at your hands, sir, the distinctions which will be conferred on them this day. It must ever be a gratification to them in after life to feel that the honourable position which they hold in this School, was known to one who, by his industry, talent, and upright bearing, both in his private and professional life, has gained for himself the good wishes of the multitude, and conferred on this hospital and on British surgery a distinguished and an undying fame.

After the prizes had been delivered to the students, Sir BENJAMIN BRODIE made the following observations:—

Although several years have elapsed since I resigned the office of surgeon to the hospital within whose walls we are now assembled, I hope that I need not assure you of the great interest which I still feel in the prosperity of the hospital itself, and in the reputation of the medical school which is connected with it. It would indeed be strange if it were otherwise. It was here that I began the study of my profession, the practice of which has been the main object of my life. Whatever knowledge I have been able to obtain, whatever advancement professionally, indebted to my son; and it is any agreeable with my colleagues in Google

suits, the hopes and fears, and aspirations of my early life.

It was my good fortune to be elected assistant-surgeon to the hospital at a very early period; and partly as assistant-surgeon, and partly as surgeon, I was attached to it during the space of thirty-two years. In that interval great changes were accomplished. The old and inconvenient building (but which, nevertheless, afforded the means of affording a great reputation to Sir Cæsar Hawkins, Dr. Heberden, Sir Everard Home, Dr. Baillie, and a still greater one to Hunter) was exchanged for this handsome and commodious edifice, having all those advantages over the former one which greater experience and the more advanced state of science could afford. Let honour be given where honour is due! In adverting to this subject it is but just that I should add that it is chiefly to one individual that we are indebted for this great improvement in our condition. It was Mr. Fuller who first proposed that the hospital should be rebuilt. Many thought it a hopeless undertaking; and it may well be doubted whether, at that time, it would have been accomplished if it had not been for his determination and perseverance, and for the spirit which he infused into those who, in the first instance, were less sanguine than himself.

It is indeed to me a source of great satisfaction to find the St. George's Hospital of the present day, so much better adapted than that of former times, to all the purposes for which a hospital is required, whether as furnishing relief to the humbler classes of society when suffering from accidental injury or disease, or as a place of instruction for those who are being educated to the medical profession. There are, however, other recollections of a less pleasing character which force themselves upon me when I recur to the period of my early connection with this institution. Of those under whom I myself studied; of those who were my fellow-students; of those who were my colleagues; and even of those who were junior to myself, how many have disappeared! how many have passed into that region from whence "no traveller returns!" One individual, however, who was assistant-surgeon here when I was myself a student, and who was my colleague afterwards, still remains among us. During the period of thirty-two years Mr. Keate and myself laboured cordially together; and I may, I believe, venture to say that not only no unkind word, but that scarcely even an unkind thought, ever passed between us. It is not for me to determine how far we were successful; but I may say that we were alike anxious, and neither one of us more than the other, to render the

hospital more and more efficient, both as a receptacle for the sick, and as a medical school. You must excuse me if I take this opportunity of expressing how much I am myself indebted to the example which Mr. Keate has afforded me as an accomplished surgeon, a man of integrity, and a gentleman. Nor are these observations altogether irrelevant on the present occasion, as I am thus led to point out to the younger members of our profession whom I see around me, by what rules they should shape their course, if they would enjoy the regard and respect of others as they advance in life.

It is not, however, to those who already belong to our profession, but to those who are now engaged in study, and who aspire to belong to it hereafter, that I now more especially address myself. Many of you are here in the very outset of your career. You are for the first time in the metropolis for the purpose of attending lectures, of dissecting, of studying disease in the hospital. You are entering on an unknown region in which you have no experience of your own to guide you; and it is reasonable to suppose that you may derive some advantage from the experience of an older person, who has formerly been in the same situation with yourselves.

And first let me impress on your minds that the next three or four years are probably the most important and critical period of your lives. You are now to lay the foundation of that knowledge on which your future character—nay, your very subsistence, is to depend. Let these few years be wasted, and you can never redeem their loss; ceaseless but unavailing regrets will haunt you through the remainder of your days. But let the opportunities which are now offered to you be properly cultivated, and twenty years hence you will reap the advantages resulting from the labour which you may now undergo, and the endeavours which you may now make to keep within due bounds the very natural desires of youth for leisure and amusement.

It is well before you enter on these new pursuits that you should satisfy yourselves as to what will be really required of you, in order that those who feel that they have it not in them to make the necessary sacrifice may turn aside to some less arduous, though probably less honourable occupation.

You must be regular and constant in your studies: you must miss nothing; for what you learn one day is not only important in itself, but is necessary to the right understanding of what you are to learn on the following day.

*"Pater ipse colendi
Hand facilem esse viam voluit."*

At no time could any one qualify him-

self for our profession without devoting himself wholly to the task. But if that were true a century ago, how can it be otherwise now, when the competition is so much increased, and when there is so much greater a mass of knowledge to be obtained than formerly!

I leave it to your respective teachers to tell you what lectures to attend, and what hours you are to devote to the dissecting-room and hospital. The advice which I shall offer you as to the conduct of your studies is of a more general nature.

Take notes of your lectures, however brief, not, in the first instance, for the sake of transcribing them (for that is better done at a more advanced period of your education), but for the purpose of keeping up your attention to the lecture at the time, and of improving you in the habit of fixing your attention afterwards. The incapability of properly fixing the attention is one of the greatest difficulties under which medical students generally labour, especially those who do not come directly from school or college. Much here depends on the structure of the individual mind; much on early habit. Where the difficulty exists, some will overcome it more easily than others; but whatever may be the amount of effort that is necessary, the effort must be made; and I venture to say that, unless there be some actual deficiency of intellect, it will not be made in vain.

For many years past I have offered to the students of St. George's hospital a prize for the best series of clinical notes of cases, with commentaries on them. I was led to do so because I was satisfied that it is only by taking notes at the patient's bed-side that a student can pursue his hospital studies with advantage. You may go daily round the wards, staring at what is going on, and every now and then listening to an observation made by the physician or surgeon, but you will never obtain any precise knowledge, either of the progress of disease, or of the effect of remedies, unless you investigate cases for yourselves, with your note-book and pencil in your hands. The notes thus taken should be transcribed in the evening afterwards. You will find them the best things to refer to (as far as they go, very much better than books) in after-life; and in transcribing them you will find that many things occur to you which would not have occurred otherwise.

And this leads me to another subject. In what are called the Golden Verses of Pythagoras we are told that before we sleep at night we should review the whole of our proceedings during the day, with reference to our moral conduct; and very good advice it is, worthy of a Christian,

though it comes from a heathen philosopher. But I would carry it still further: always in the evening review your studies of the previous day, and endeavour to recal to mind the principal facts which have been presented to your observation. This will not only impress them on your memory, but it will give you the habit of thought and reflection. For observe, that it is not sufficient for you to store your minds with knowledge: a member of the medical profession, above most others, must learn to arrange his knowledge—to view facts in their relation to each other—in a word, he must be accustomed to think. If knowledge be necessary for him, it is not less necessary that his mind should be so trained that he may know how to use it. However well-informed he may be, he will otherwise prove to be a very inefficient practitioner.

There is one other subject on which it may be well that I should offer some advice to the junior part of my audience. You are now placed, for a time at least, in this great city, where there is much to interest you—much to attract your attention—besides those higher objects for which you are assembled here. You will have many inducements to be idle as to your studies; but let me urge you to be careful not to yield to the first temptation. If idle habits are once contracted it is difficult to alter them; and it is not less difficult to be rid of idle companions. I need not repeat to you, that idleness is incompatible with the acquirement of knowledge. But there is much more behind. Idleness leads to dissipation, and dissipation to extravagance; and then come debt, disgrace, loss of self-respect, moral degradation. Be careful in choosing your companions; exercise a proper self-control in the first instance: make it your business to pass through the period of your professional education not only with the character of diligent students but of gentlemen, in the best sense of the word; and you will be sure of being amply rewarded by the enjoyment hereafter of professional success and the respect of the world at large.

Gentlemen! I offer you this advice not because you are medical students, but because you are young men. I do not believe that you are more in want of such admonition than others of the same age. I know not what medical students may be in other schools; but, as to those belonging to the school with which I was formerly so long and so intimately connected, I feel it but just that I should express my sincere conviction that there was always as large a proportion of young men diligent in the pursuit of knowledge, and decorous in their general conduct, as is to be met with in

any class of society. Of course there were, and always will be, exceptions to the general rule; and you and I, and all of us, who would maintain the high character of our profession, must be anxious that these exceptions should be as few as possible.

To you, gentlemen, who have been the successful competitors for the prizes given annually by the different teachers of this school, I offer my sincere congratulations. If you have gained honour for yourselves, you have also done good to others; for example is better than precept, and there is no one among you who has not exercised a wholesome influence on his fellow students. Let me advise you to pursue the same course through life, recollecting that even as practitioners you must still be students. Knowledge is endless; and the most experienced person will find that he has still much to learn, many opinions to modify, and errors to correct. You are entering on a profession, which is good or bad according to the manner in which it is pursued. Let me offer you some suggestions as to your conduct in it. On no occasion allow anything to interfere with the strict performance of your professional duties. Whatever you undertake to do, that do to the very best of your ability, sparing neither thought nor trouble, whether it be in the case of the poor man, to whom you give gratuitous assistance, or of the rich man, who remunerates you liberally for your attentions. Consider yourselves as being engaged not in a trade, but in the cultivation of a noble and interesting science. Let it be your first object to deserve and obtain the good opinion of all classes of society with whom you come in contact, not only as being skilful practitioners, but as men of honour and integrity. You will then be in that independent situation which will place you above the caprice of the foolish, and also above the necessity of stooping to obtain the favour of any individual. Do justice to others; but do justice also to your profession and yourselves; always bearing in mind that those who are in any way usefully and honourably employed, have a much higher place in the scale of existence than those useless and selfish persons, who live only for themselves, however high their rank—however large their fortune.

TWO CASES OF PURULENT DEPOSITS IN THE HEAD, REMAINING LONG UNATTENDED WITH BAD EFFECTS.

1. A HUSSAR, a healthy man, 26 years of age, in the beginning of 1840, fell from his horse, and struck his forehead. Some weeks afterwards he engaged himself as a labourer. In 1842 he again entered a

hussar regiment. A slightly-elevated tumefaction remained as the only trace of the accident. His health was good, and no impediment existed to his admission into the army. He performed all his duties for three years, during which time also he received promotion. He was very temperate and orderly. In the spring of 1848 he took part in very severe service: the pressure of his cap irritated the tumor on his forehead. In December 1848 he was suddenly seized with symptoms of cerebral oppression. During the night the tumor had burst, and several spoonfuls of offensive pus had been discharged. The opening was further enlarged, and other treatment adopted, but he died on the 31st December.

On inspection there was found a fistulous opening into the cavity of the cranium, with thickening and discoloration of the dura mater, especially at its attachment to the crista galli. Between the dura mater and the frontal bone were about two teaspoonfuls of fetid pus—the remains of that which had been discharged a few days before.

This case has a medico-legal interest, inasmuch as had his death followed a blow inflicted in a quarrel, his antagonist might have borne the charge of homicide.

2. A cuirassier, 21 years of age, who had been nine months in the service, and was of a good constitution, was admitted into the hospital on the 19th May. He was suffering from catarrhal fever. He did not complain of headache, but of a peculiar confused feeling in the head. The patient ate and drank, and was up and about the greater part of the day.

He had, like the preceding patient, been exposed to hard service with his company. Exposure to cold was the cause of his illness. The prognosis was good—the treatment antiphlogistic.

On the 23d May he was considered convalescent.

On the 24th he suffered from severe relapse, with symptoms of congestion of the brain. These symptoms all became worse, and he died on the night of the 25th.

On inquiring into his history it was found that some time previously he had received a blow on his head; that, four months before, he had also had syphilis; and in his youth had always been rather deaf in the right ear.

On opening the head, about two ounces of thin pus were found in the posterior fossa of the base of the cranium on the right side, lying between the dura mater and the fibrous portion of the temporal bone. Deposits of pus were found in the inner ear, and the mucous membrane of the cavity of the tympanum was destroyed. The arachnoid membrane was unusually vascular.—*Casper's Wochenchrift*.

REMARKS ON THE
VITAL STATISTICS OF THE
BOROUGH OF PLYMOUTH,
FOR THE YEAR ENDED ON THE 30TH OF
JUNE, 1850.

By DR. W. HAMILTON.

[Continued from p. 573.]

IN 1846, after an interval of fourteen years mercifully granted for preparation, as we learn from the valuable report on the sanitary condition of the town, drawn up by the Rev. W. J. Odgers with that ability, philanthropy, and zeal, for which he is so pre-eminently distinguished, out of 4,045 houses at which he made personal inquiries no fewer than 1,763, or 43·58 per cent of the entire number, were either not at all drained or but imperfectly so, as is seen by the following table:—

Districts.	Undrained.	Badly drained.	Total.
Saint Andrew	512	589	1101
Charles . .	444	218	662
Total . .	956	807	1763

I have no means of ascertaining the amount of improvement effected in this respect during the last four years without a personal inquiry at each house, to which my physical strength is unequal. But although I believe it to have been considerable, much remains yet to be done; and there is but too much justice in the remarks made by Dr. E. T. Roe in a communication to the "Medical Times" of the 3rd of August, 1850, where he says, at page 117, that—

"When the disease died away, the evidence of a desire to ameliorate the condition of the poor died too; and they, neglected and forgotten, have, of course, resumed their former habits, and returned to their accustomed haunts. This town is an example of the truth of my statement; nothing was done until cholera was at our very doors;

then more was attempted than could be completed; and now the poor are rapidly sinking back into pollutions as bad and as numerous as they were twelve months ago. In saying this, I make no charge against our local authorities; they, probably, in common with many others, thought cholera might not visit us; and if it did not, expense would be unnecessarily incurred, and alarm causelessly excited, by any sanitary precautions being commenced in the time of panic; but now no such reasoning avails. The cholera came and found us unprepared: it worked out its fatal problem with unerring accuracy: the abodes of misery it desolated, and scattered their plague-struck population to carry the devastating pestilence far and wide. Should it again approach, cesspools, unventilated houses, a scanty supply of water, and undrained streets, are the internal foes that will, if allowed to continue, open our gates to the enemy. The necessary measures may be costly; but money spent in improving the physical condition of the poor is wise economy; by making their homes more healthful, we cultivate and raise their moral standard, and check the expenses of criminal justice; for it has been amply shown that the great centres of disease are at the same time the nurseries and fortresses of crime: we check the expenses of pauper relief; for a short-lived population is generally a surplus population, not only because those who are reckless of life will be careless of all its obligations, and will be poor and vicious, but because the tendency of early deaths is chiefly to shorten the existence of those who produce more than they consume, and to increase the number of those who must be dependent upon the charity of others."

It is, perhaps, known to but few that the last visitation of cholera cost this town, independently of the loss of life and injury to trade, which were its unavoidable results, upwards of £4000 in money, which, had it been gradually expended during the eighteen previous years in sanitary improvements, and in endeavours to obtain a repeal of the window tax, to which is attributable much of the insalubrity of our houses, the burthen would have been less felt by the inhabitants. Very few would have taken plan and perhaps, to

the case with the hurried and often reckless expenditure which has taken place. The following is the cholera balance sheet, extracted from the annual account presented by the Guardians to the rate-payers at the election which took place on the 14th of May, 1850:—

BOARD OF HEALTH.					
An Account incurred under the Board's Directions for Cholera.					
Dr.	£.	s.	d.	CR.	£. s. d.
For building hospitals, furniture, &c. . .	461	16	5	By paid as per Treasurer's account . .	2431 14 3½
Medical attendance, cab-hire, &c. . .	1566	18	3	Balance due to medical officers and tradesmen . . .	1984 5 3½
Drugs supplied . .	553	19	1		
Butchers, bakers, grocers, and other tradesmen, for various supplies . .	864	18	4½		
Coffins, burial fees, attendance, &c. . .	577	1	2½		
Nurses, costmen, labourers, &c. . .	391	6	3		
	4415	19	7		4415 19 7

Dr. Snow regards impurities contained in the water employed for culinary and drinking purposes among the most active means of diffusing the poison of cholera; and such, no doubt, has been the case in London and a multitude of other localities; but such a cause must have operated very partially, if at all, in Plymouth, where the great bulk of the inhabitants have their supply of water of the purest description from the town leet, which has its source at a distance of some eighteen or twenty miles in the more elevated regions of Dartmoor, whence it was brought originally by Sir Francis Drake above two centuries and a half since, and which the municipal authorities preserve most carefully from contamination: such is the purity of this water, that a quart yields on evaporation less than two grains of residuum, chiefly consisting of hydrochlorate of soda derived from the marine spray driven by the south-western winds into the interior from the basin of the Sound and the English Channel.

Until the decennial enumeration which is to take place at the end of next March shall have been completed, I am without any means of ascertaining the actual number of houses existing in the borough either at the present moment, or in 1846, when Mr. Odgers collected the materials for his important report. Judging, however, from the multitude of new

streets that are daily starting into existence in every possible direction, we might be led, not unreasonably, to consider the town as more than doubled in size since the enumeration of 1841; and it is far from improbable that such a conjecture would not err greatly from the truth. But to assume a less questionable basis for our calculation, let us compare the amount of population returned in 1841 with the additions made to it from natural causes, irrespective of the disturbing influences of immigration and emigration, of which as yet we have no means of judging, in the intervening time, and endeavour from thence to form an unexaggerated estimate of the number of houses at present in actual existence, or in progress. The population on the last enumeration was 38,527; and, according to an estimate based on the excess of births over deaths during the nine years which ended on the 30th of June last, the population had increased to 39,266 on the 1st of July, or nearly 7·5 per cent. in that time, notwithstanding the supernumerary mortality of 1849 from cholera.

In 1841 the number of houses returned was 4,298 inhabited; 228, or 5·3 per cent., void; and 38 building; making an aggregate of 4,526 habitable houses, and 38 progressing to completion. If we assume 7·5 per cent. a rate closely approximating the increase of population arising from births, as that of the

multiplication of buildings to accommodate such an augmentation of inhabitants, we shall have 5000 for the probable number of houses inhabited at present,—a number which we may well conceive to fall short of the truth by at least 2,000 or more. Of the number of houses visited by Mr. Odgers in 1848, when the estimated population was 88,405, or nearly 2·4 per cent. less than at present, 753, or about 18 per cent., were unsupplied with town or leet water; but of these a large proportion was provided with rain water or water from wells or pumps.

Now, with the exception of the well or pump water, the supply to more than nine-tenths of the inhabitants consists of the very purest quality, and placed beyond the reach of such contaminations as Dr. Snow suggests; while, from the moderation of the annual charge, graduated according to the rental of the house, the poorest inhabitants are enabled to participate in the supply: so that, with the exception of the minute fraction dependent upon wells and pumps liable to contamination from the infiltration of sewer and cesspools, the inhabitants of Plymouth enjoy a larger amount of protection from this fertile source of disease than those of most other towns throughout Great Britain.

It must be admitted, indeed, that, although not originating in them, cholera, after it had established itself, raged with its most fatal fury in those localities where the supply of water was most scanty, and the sewerage most imperfect: but this by no means establishes the fact of its having been produced by those causes: it merely shows that the soil was prepared for the reception of the seed, which, once planted, sprouted forth with more than its ordinary rapidity and vigour, as Dr. Roe very justly observes in the paper already quoted:—

“When the air of a town is infected with cholera poison, local causes, without contact, may give rise to isolated cases of the disease, and that, when imported into a town the sanitary condition of which is healthy, it will find nothing to feed upon, as has been the case at Exeter and elsewhere; but if, on the other hand, it meets with a hotbed of filth, misery, starvation, and disease, then such scenes occur as have twice within the last eighteen years been enacted in Plymouth, and death mows

down those whom a defective local legislation had allowed to rot while living.”

Such “a hotbed of filth, misery, starvation, and disease,” awaited the reception of cholera in Stonehouse and the adjoining lanes, in which, prior to 1849, there was a total absence of drainage; and, in place of feeling astonishment at the severity of the outbreak in that and similar quarters, the only subject for surprise is, that it did not commence there, and radiate from thence to other parts of the town. Bath Quarry and Stonehouse Lanes are situated at the base of the elevation upon which Eldad stands, and thus receive the full benefit of the impure filtration which percolates the soil above from the two cesspits into which the whole of Eldad, as Mr. Odgers informs us, was drained in 1840; and from that time, I believe, up to the moment of the invasion of cholera in 1849.

Quarry Lane, as we learn from Mr. Odger's report, contained at the time of his inquiries ten houses occupied by 135 individuals, or 13·5 to each house; and for the supply of these people there was then but one water-cock, and one pump. Stonehouse Lane, with 69 houses and 825 inhabitants, or 12·3 to each house, had the leet water supplied to but ten of the houses, or about 18 per cent. of the whole, the remaining houses being provided with this necessary of life by hand carriage from the leet which passes by “No Place Inn” for the service of the Royal Naval Hospital, at a considerable distance, and on the summit of the ridge; while Stoke Lane, with 21 houses and 154 inhabitants, or 7·3 to each, is wholly dependent on pumps for its supply, not one house having the benefit of the town water, and only eight of the houses, or 18 per cent. of the number, being provided with pumps, the water of which is much contaminated by infiltration. And in these three localities so peculiarly adapted to the spread of mortality, we find 77 deaths, or above one-eleventh of the whole mortality from cholera, took place. But if such was the amount of the mortality in this ill-drained, ill-watered, and most impure part of the town, ought we not to expect a proportionate amount in other places similarly situated? To answer this question, let us look to the mortality and condition of Market Alley.

Market Alley is a close, narrow, ill-ventilated passage, leading by an archway under one of the houses in Bedford Street across into East Street, from which a doorway gives an entrance into the south side of the market-place: so that at either extremity it is out off from free ventilation. The houses which form this alley are lofty, and inhabited by the poorer classes, of whom, as the report already quoted acquaints, 207, or 20·7 to each, occupy the ten houses which form it: of these ten houses, but three, or less than one-third, are provided with town water; and not one of them has a cistern or tank to retain the water for the alternate days on which there is no supply. Yet, notwithstanding this density of population, this imperfect ventilation, and this defective supply of water, we find the mortality of this unhealthy passage confined to a solitary death from cholera on the 29th of September.

In Union Street, that great artery of communication between Plymouth, Stonehouse, and Devonport, which, though little elevated above high-water mark, is one of the widest, best built, and best ventilated parts of the town, where all the houses are occupied by persons in comfortable circumstances, and well supplied with the town water; where no assignable cause for epidemic diseases presents itself to the eye; and where no impurity from infiltration can have tended to introduce the malady,—here the earliest case of cholera appeared, and here the two first deaths occurred four days before the eruption in Stonehouse Lane and its pestilential vicinity. Had the disease originated among ourselves from the causes to which it was commonly ascribed elsewhere, we should naturally have looked for it in that concentration of filth and poverty, rather than in Union Street, where the first death took place on the 4th, and the second on the 7th of July; and two which remained were on the 8th of July and 19th of September. The two first of the thirty-seven deaths which took place in Quarry Lane did not happen before the 8th of July; and the five last on the 18th, after which all cases were taken to the hospital as they arose. In Stonehouse Lane the first three out of the forty fatal cases there were on the 9th of July, five days after its appearance in Union Street, two occurred on

the day following; and from one to two deaths daily for the next nine, after which solitary deaths took place on the 24th and 27th, on the 1st, 2nd, 7th, 14th, 16th, 17th, and 21st of August; two on the 18th; and the four last on the 7th, 8th, 10th, and 21st of September.

But in Higher Street the outbreak was almost wholly condensed into the third week of the third month of the pestilence, only two deaths having taken place during the whole of July and August,—namely, on the 25th of the former, and 31st of the latter; and three deaths out of the forty-two in October, the great bulk of the mortality taking place between the 13th and the 24th, in which the deaths amounted to thirty-five, of which number as many as nine were on the 16th, six the day following, and eight on the 18th.

Higher Street occupies a position on the eastern side of the town analogous to that of Quarry and Stonehouse Lanes on the western, being at the base of the hill crowned by Gascoyne Terrace, with which it is connected by the steep ascent of Gasking Street. This street, which in 1846 contained 508 inhabitants, is classed by Mr. Odgers among those which are drained (though, he adds in a parenthesis, imperfectly), in which respect it is far better off than Stonehouse Lane, in which, prior to the late visitation of cholera, not a trace of drainage was to be found. But here it must be admitted that the existence of sewerage in the one, and its total absence in the other case, throws a shade of suspicion over the opinions of those who ascribe the mortality of cholera exclusively to defective sewerage.

The formidable outbreak of cholera in Higher Street on 14th of Sept. has been traced to a woman who occupied a room by herself at the top of one of the most densely tenanted houses in the street, containing, if I recollect aright, somewhere about 60 individuals, steeped for the most part in the deepest poverty and wretchedness. This lonely and unfortunate individual having been attacked with cholera in the silent darkness of the night, perished without help in the solitude of her room; and it was not for a considerable time after her decease that she was missed by her neighbours, who went to her door to learn the cause of her non-appearance.

After knocking and calling without obtaining a reply, they broke open the door, and found, as they suspected, that she was not only dead, but considerably advanced in decomposition. The scent, which diffused itself through the whole house immediately after the door was burst open, I understood to have been intolerable, and to have resembled that of which the unfortunate Mrs. Fortescue complained on meeting the funeral procession in Bilbury Street; and there was an equal correspondence in the results: cholera almost instantly made its dreaded appearance, and the mortality was only exceeded by the panic. Among other inmates of this ill-fated dwelling was one who kept a dairy in one of the lower apartments. To the milk in this apartment, if report speak true, the cholera communicated a portion of its destructive poison, and thus extended its ravages to other and more distant localities, where this contaminated milk was consumed. How far this statement is fact, or how far it is the creature of imagination, I have not been able to ascertain: and as the inquiry is, as I have been informed, in the hands of one better qualified for the task than myself, I willingly resign it to him, in the hope that he will not withhold the result from the world.

The origin of cholera in the malignant form in which it has depopulated the world since the latter portion of the eighteenth century is buried in the profoundest depths of obscurity, since I have not been able to find any authentic or distinct account of it farther back than the year 1781, when it made its appearance among the British troops, 5000 in number, stationed at Gangam, about lat. $19^{\circ} 20'$ N., and long. $84^{\circ} 40'$ E., on the coast of the Circars, 535 N.E. of Madras, where, in the brief space of three days, it consigned to the hospital or the tomb above half the number. In the following year it extended to Madras, although in a somewhat mitigated form; and after a delay of twelve months more reached Hurdwar, near lat. 30° and E. long. $70^{\circ} 20'$, where, besides invading both the civil and military inhabitants, it swept off no fewer than 20,000 of the pilgrims who frequented that holy place. After this we lose sight of it till 1817, a period of four-and-thirty years, during which we can hardly suppose it to have been dormant or extinct, although its ravages might

have been so far confined within the bounds of moderation as to attract little attention.

In the "Wanderings of a Pilgrim" already noticed, the talented authoress gives us the following account of this frightful scourge, obtained from conversations with her physician:—

"Our physician has just quitted us: we had a conversation on this dreadful malady that has wrought us so much misery; he, says—'Cholera is an endemic of Ceylon; from the year 1813 to 1817 I never met with it in India. In 1817 it burst out in a mad-house of which I had the charge, and the patients confined there died daily in the course of a few hours after the first seizure. The horror produced amongst the unfortunate insane was so great, that many became perfectly sane. A man who had attempted to destroy himself in a fit of phrensy, by cutting his own throat and stabbing himself, became perfectly sane, and, coming to me, intreated to be allowed to leave the mad-house, as he was sure he should die of the cholera. It was utterly impossible his request could be granted at the moment: in the course of the week he fell a victim to the malady.'

"Our medical man added, 'The causes of cholera are unknown. I know that the disease is often confined to a space of two or three hundred yards; for instant deaths occurred daily in the mad-house. In the jail, which contained five hundred prisoners, and was not three hundred yards distant, not a case appeared. I was so well convinced of the disease being confined to a certain spot, that I applied for leave to remove all the insane to a spare room in the jail: from the time of their entering the jail, not one man died of cholera. The environs, as well as the interior of the mad-house, were quite clear and pure; *no stagnant water*; nothing that could generate disease in any shape.

"I mentioned that it was supposed our beloved one had been exposed to the baneful influence of cholera in passing through Arcott, where it was known to be. 'Certainly not: *it would not lurk about a person twenty-four hours*. Until the moment she was seized, she was in perfect health. I once saw a man, previously in good health, seized with cholera: he was *sitting in a chair, talking to me*; he dropped; his nervous power was quite prostrated: he was perfectly sen-

sible the whole time, and died in a few hours.' I asked if his sufferings were not very great? The physician replied, 'I should think not; from the extreme want of life in the body. The effect of the illness is such, that the vital spark is almost extinguished while still the body breathes.'

"He said, 'You should not grieve at the speedy termination of her illness; from severe cholera it is hardly possible to recover. Those who do recover, generally linger on for twelve or fourteen days, and then expire in a melancholy state: it is better it should terminate at once.'

"It came from Ceylon, and broke out with dreadful severity in 1817, especially in what we call Bengal, which is one hundred miles around the presidency; since which it has raged partially in Oalcutta and all the lower provinces; also in the higher; but in the central provinces, in which Allahabad is situated, it is very rare, only one case of cholera having occurred during the last two years at this station. At Berhampoor it is dreadfully prevalent: the 48th regiment quitted this a short time ago by the river, and lost nine men at that place. No diet, no care, can avail. Our medical man said, 'I can compare it to nothing but a flash of lightning: its effects are instantaneous; the nerves from the first moment are powerless, dull, and torpid.'

"If I were to be seized with it to-morrow, I should only strive to resign myself quietly to my fate, feeling that to strive against the malady is hopeless: in fever you have hope; in cholera scarcely a shadow of it: it is better not indulged; but the disease is so powerful, it dulls the senses—mercifully dulls them" (pp. 202 et seq., vol. i.)

Great as the destruction of human life by cholera, the amount sinks into insignificance on a comparison with the wholesale slaughter of which we have accounts from other places, in Asia more especially.

It was not till 1817, as is stated in the passage just quoted, that cholera developed itself fully in the character of a wide-spreading and irresistible epidemic, mowing down nearly the entire population of some localities, setting at nought all the puny efforts of man, and carrying dismay into the boldest hearts.

Finding in this year an appropriate soil in the marshy and pestilential

swamps which, under the name of Sunderbunds, constitute the feverish Delta of the Ganges, it made its onslaught on the town of Jessore and its sixty thousand inhabitants, one-tenth of whom were, in the space of a very few weeks, erased from the books of the living. In less than a month it reached Calcutta, at a distance of one hundred miles southwest of Jessore, where two hundred daily victims were insufficient to sate its appetite for life.

[To be continued.]

POISONING BY THE SEEDS OF *JATROPHA CURCAS*. BY R. J. FARQUHARSON, M.D., ASSISTANT-SURGEON U. S. N.

Two of our men, being ashore at Porto Praya, Cape de Verdes, tasted the seeds of the *Jatropha curcas* (which grows in great abundance on these islands), and finding them pleasant, ate of them, one to the extent of a handful, the other being satisfied with three or four. In both cases vomiting and purging of a violent character came on in the course of an hour; and in the instance of the man who had eaten but a small quantity, the effect only extended thus far. In the other case more alarming symptoms rapidly supervened. The muscles of the extremities were contracted by violent spasms; the patient was affected with dizziness and vertigo, accompanied by great restlessness; the respiration was quick and panting; the skin became cold and moist, and the pulse small, thready, and intermittent; the heart's action was very irregular, and so weak that the impulse against the walls of the chest could with great difficulty be perceived. These effects of the poison upon the nervous system continued for the space of several hours. The seeds eaten were ripe, and of the kind used in small quantities by the inhabitants as an active purgative.

The treatment consisted in the free use of anodynes and stimulants, after the continuance of vomiting and purging for a time rendered it probable that all the offensive matter had been discharged from the intestinal canal; together with the application of a large mustard poultice during the state of depression. About five hours after the commencement of the attack, reaction occurred; and shortly afterwards the patient fell asleep, and waked the next morning with no other ill effects remaining than a slight irritability of the stomach and considerable debility.—*American Journal of Medical Sciences* for July, 1850.

OR
SOME OF THE MORE PRACTICAL
POINTS CONNECTED WITH
THE TREATMENT OF
DEFORMITIES.

BY EDWARD F. LONSDALE,
Assistant-Surgeon to the Royal Orthopaedic
Hospital.

[Continued from p. 357.]

*On the Nature and Causes of Deformities
of the Hip-joint, considered generally.*

I SHALL next proceed to consider the deformities that are met with about the hip-joint; and they admit of being divided into three classes—viz., where they arise from displacement of the head of the femur from the acetabulum, with little or no contraction; those where there is contraction only, without displacement; and, finally, where there is both displacement and contraction. The latter is by far the most common. The causes may also vary, of which four principal ones may be mentioned—1st. Inflammatory diseases, such as simple acute inflammation, rheumatic inflammation, and scrofulous inflammation, the last being the most frequent. 2d. Spasmodic or gradual contraction of the muscles, and more particularly of the flexors of the hip, depending either upon disease of the spine, upon rheumatism, or upon hysteria. 3d. Injuries in the neighbourhood of the joint, or to the joint itself, may cause permanent lameness, and alteration in the natural relative position of the femur with the acetabulum. 4th. Congenital deformities of the joint may exist, where the femur is dislocated either on one or both sides. Another cause might perhaps be mentioned—viz., a rachitic condition of the bones generally, where the pelvis becomes distorted, and the shape and relative position of the neck of the femur and trochanters also are altered to an extent to produce external deformity with regard to the shape of the joint, though the interior may be perfect and natural in structure. It will be best, then, to consider the subject as arranged in the following table:—

Varieties.	Causes.
Displacement of the bone without contraction.	Disease of the joint, with more or less destruction of the bones. Mechanical violence. Congenital malformation of the joint.
Displacement of the bone with contraction.	Disease of the joint, with more or less destruction of the bones. Mechanical violence.
Contraction of the joint without displacement.	Spasm (temporary or permanent) from rheumatic and other inflammations. Disease and irritation of the spine and spinal marrow. Hysteria.
Deformity in external shape only.	Rickets. Mechanical violence.

Displacement of the Bone without Contraction of the Joint.

The head of the femur may be displaced directly upwards, and rest upon the ilium immediately above and very slightly behind the margin of the acetabulum, causing a shortening of the whole limb, without any other alteration of its relative position. This condition of the joint is evidenced by the measurement of the limb, as well as by feeling the trochanter—and, in many cases, the head of the femur—in a position they ought not naturally to occupy. There may be no contraction of the joint forwards in a state of flexion, nor complete impediment to motion; for there may still be the power of bringing the knee backwards and forwards to a certain extent. The toe is pointed downwards, though the patient can, in many cases, bring the foot nearly flat upon the ground (of course by bending the body to this side), which seldom can be done when the displacement is attended with contraction of the hip as well; for the knee not being in a straight line with the body, the only part of the foot that touches the ground is the toes, and this also at the expense of the perpendicular bearing of the body, which has to be thrown over to this side.

In the cases of disease of the joint, where this displacement upwards of the femur exists without contraction forwards, I believe it will generally be found that the destruction of the capsule of the joint has taken place with-

out much pain or constitutional disturbance to the patient, and in most cases very rapidly; so that no lengthened confinement to bed (if any) has been required, and, from the absence of pain, the joint has not been placed in the flexed position, to take off the strain or pressure on the anterior part of the joint which no doubt exists in the acute cases where the inflammation is very active. The head of the femur, as well as the margin of the acetabulum, may also become more rapidly absorbed in some cases than in others, and so allow of the more easy displacement of the bone upwards than when the head of the bone is dislocated without being much altered in form, which then causes it to be thrown more backwards, and the knee forwards, and so cause contraction of the muscles in this direction. These cases, however, are of the rarest kind, the majority being accompanied with great pain and contraction of the hip forwards, and requiring the patient to remain in bed for a longer or shorter period, according to the severity of the symptoms.

Where mechanical violence is the cause of the displacement, as in some severe kinds of injuries, one of two things must occur: either the bone must be dislocated, or the neck of the femur must be fractured, or the greater trochanter be split very high up. In the latter cases—viz., fractures—it is not at all uncommon to find the limb much shortened from the femur being drawn upwards, without any contraction forwards—in fact, in by far the majority of cases of fractures through the neck of the bone this is the position the limb usually takes. In the former, however, viz., in dislocation of the femur upwards—it is unusual to find the limb to keep its straight position, it generally being flexed and inclined to the opposite (I am of course only speaking of dislocations upwards or backwards, or both). The cases in which it does occur are very rare, and are always, so far as my own experience has gone, in children about or under the age of puberty. The reason of its being rare is, that dislocation of the femur at this age is extremely rare; force, if applied to the bone, generally producing fracture in some part of its length, and so arresting the violence before it can tell upon the joint. When it does occur,

the absence of any contraction in the direction of flexion is to be explained by the smallness of the head of the femur at this age, as well as by the flatness of the ilium and margin of the acetabulum, which allows of the bone resting directly upwards instead of being tilted upwards and then backwards. There is generally less impediment to the motion of the bone in these cases than might be expected, for there still remains the power of flexing the thigh forwards; and, after a time, the patient can bear his weight upon the limb—of course walking lamely, from the shortening there exists.

I once saw a case where there was shortening of the limb without contraction in the direction of flexion, in the adult, after an injury, which is interesting on account of its extreme rarity. I have described it elsewhere.*

A man received a severe blow from a fall, which told in a direction on the femur to produce dislocation of the head of the bone. The patient was admitted into the Middlesex Hospital, with some though not all the symptoms of dislocation upwards in the direction of the ilium. The limb was shortened, and the trochanter was by measurement at a higher level than natural, and the head of the bone could also be felt, which of course at once indicated displacement. The position of the knee and foot, however, were natural, being neither inverted nor everted, combined with which there was power to flex the thigh forwards almost to the natural extent. The limb could not be elongated by extension, nor any crepitus be produced. The man died of other injuries received at the same time, one of which was fracture through the sacrum. On making the post-mortem, there was found to be fracture of the upper and posterior margin of the acetabulum, which was levelled off to the ilium; and upon this fractured surface the head of the bone rested.†

There are other cases also of displacement of the head of the femur by violence, as in fractures directly through the acetabulum, where it is driven into the cavity of the pelvis. These are rare.

* Treatise on Fractures, p. 267.

† The preparation is in the Middlesex Hospital Museum.

Of Congenital Displacement of the Head of the Femur.

This is the most complete form of displacement without contraction of the hip-joint that exists. It consists in a complete dislocation of the head of the bone upwards on to the dorsum of the ilium, the patient having the power of bending the joint, if so it may be called, at pleasure, being able to bear the weight upon it, and, if of an age to do so, to walk also. There is of course lameness and awkwardness in his gait, consisting of a hobbling, "waddling" motion, from side to side. The peculiarity of these cases is, the loose way in which the head of the femur appears to be connected with the pelvis, and that the patient should still have so much power over the limb, and be able to bear the weight of his body upon it. It will be found on examination that the bone can be easily drawn down, till the head of it rests in the place where the acetabulum ought to be, and then is either drawn back again to its abnormal position by the action of the muscles, or can be easily pushed there with but a very slight force.

I have not had an opportunity of dissecting a case of this nature to ascertain with certainty the precise condition of the joint. All the symptoms, however, lead to the supposition, that from some cause in utero the ligaments proper to connect the head of the bone with the pelvis are never formed, or else that they are so long as to allow of the degree of displacement that is found to exist. The bones themselves may also take some share in the deformity, either by the head of the femur not being properly developed, or by the absence of the acetabulum. The acetabulum at the time of birth, however, is always very shallow, and not sufficient to prevent displacement more frequently than is found to occur were it a cause of the displacement. Dupuytren mentions having had the opportunity of dissecting but few cases.* The appearances observed in one I shall here give; they will be found to explain the cause of the difficulty, if not impossibility, of doing much in the way of treatment in these cases:—The subject was a man of 75 years of age, who died of the effects of a long-standing stricture of the urethra, having been

born with congenital dislocation of both thigh-bones. The following is the account of the condition of the ligaments and bones which naturally form the hip-joint:—"On the left side the old cavity (the acetabulum) was not more than an inch wide in its greatest diameter; it was very shallow, rough, and filled with a fatty substance—yellow, of the consistence of oil, and almost of an oval form. The external iliac fossa had in front of the sciatic notch a wide shallow depression, covered or lined with a thick periosteum, having almost the appearance of an articular cartilage: this place was contiguous to the head of the femur. The head was diminished in volume, a little flattened, unequal, without any trace of the insertion of the internal ligament; was covered with an articular cartilage, but thinner than in the natural state. The articular fibrous capsule formed a true sac, the points of insertion of which were the superior and inferior edges of the old cavity. This sac filled the place of a bony cavity on this side, and by its length allowed the ascent of the head of the femur into the depression just spoken of, the space through which it could move being about three inches. The thickness of this sac was very considerable, its density almost cartilaginous.

"On the right side the old cavity was a little larger: the interior had the same appearance as the other. The external iliac fossa, instead of offering, as on the opposite side, a simple depression, presented in front of the great sciatic foramen, towards the edge of the space comprised between the anterior inferior and anterior superior iliac spines, a wide and deep cavity with bony margin, rough, and unequal. The head, more voluminous than that of the opposite side, had kept its form better; it was, like the other, covered with an imperfect articular cartilage, and the interior of these articulations was lined with a synovial membrane. The capsular ligament was not so thick as on the left side, although its extent was not confined to the margin of the abnormal cavity. But on this side the head of the femur lodged against the bony edge, found there a solid "point d'appui;" while on the left the great strength of the fibrous sac supported alone the ascent of the limb by its resistance to the weight of the body."

* *Lçons Orales*, t. III. p. 205.

I have quoted thus much of Dupuytren's paper, as the points detailed will explain the cause of the external appearance met with in these cases, as well as the awkwardness in the gait, and the difficulty in supporting the weight of the body. There is a peculiarity in these cases when the patients arrive at an age to walk and run—viz., that they do the latter with less difficulty than the former; they are able to run without the same appearance of awkwardness and lameness, the explanation of which, as given by Dupuytren, is no doubt the correct one. He says: "It might seem singular at first sight that running and jumping are performed with less difficulty than merely walking. It is nevertheless so: in this kind of locomotion the energy of the muscular contraction, and the rapidity of transport of the weight of the body from one member to the other, renders almost insensible the effects of the want of an acetabulum, and of the fixedness of the head of the femur.*

"The immediate cause of the displacement of the head of the femur in these cases of congenital dislocation is not so easily explained. The following questions have been asked:—Has there been any disease in the fœtus while in the mother's womb, and cured before birth? Could it have been the result of an effort, or of violence, which made the head of the femur move from the acetabulum, and this latter part have been obliterated without disease, or only because it remained without employment, and consequently useless? Could nature have forgotten to shape a cavity for the head of the femur or this cavity, which results by the joining and union of the three pieces of which the ilia are composed? Could it be imperfect, owing to any obstacle in the formation of the bone, as supposed by M. Breschet?"†

My own impression is that there is no occasion to find causes to explain the dislocation of the head of the bone in these cases, if the fact be that there has been none, which I am inclined to think the case; believing that the hip-joint has never been perfected, and consequently that the head of the femur has not been in contact with the acetabulum from the very commencement of the development of the fœtus. I look

upon it as an original arrest of development in the hip-joint, the ligaments never having been properly joined to keep the bone in the joint, or else that the bone itself is never, from some cause or other, placed in its proper position to be opposite to the acetabulum, and that the ligaments consequently accommodate themselves to this altered position, and never gain the power of fixing the bone in its natural place: were it owing to any position or movement of the child "in utero" we no doubt should meet with it more frequently. The following circumstance also favours the supposition of some original defect in the development of the joint being the cause of the want of the proper apposition in the bones—viz., that it runs in families:—Dupuytren relates the following case of the relations of a female whom he had the opportunity of seeing:—"Two of her aunts, on the maternal side, who died at 70 years, had been affected with lameness from earliest life. They said besides that they had always limped. They had high and large hips, very projecting, and they walked with their elbows out behind, hobbling like ducks. The father of Margaret had a sister deformed from birth on the right side, who died at the age of 80 years. Another sister, well formed, gave birth to a girl who had a shortening of the right limb."

The peculiar feature in these cases of congenital dislocation is the facility with which the limb can be elongated by placing the patient on his back, and then making extension upon it, or can be moved upwards and downwards without any apparent resistance being offered: the muscles draw the bone upwards again when the extension is discontinued, though they oppose little or no resistance to its being brought downwards. In many cases, as might be expected, when the patient lies down, the bone approaches nearer to the acetabulum without any extension being made, owing merely to the weight of the body being removed, which pushed the pelvis past the head of the bone when in the erect position.

The second variety of deformity of the hip-joint—Displacement of the bone with contraction.

This is by far the most common deformity met with about the hip, and in fact ranks amongst the most frequent

* *Leçons Orales*, t. iii. p. 222.

† *Loc. cit.*

of any kind of deformity met with in this or any other part of the body generally. So common is it, that not only do those connected with institutions appropriated to these cases see great numbers of them, but general hospitals are seldom without them. They are, unfortunately, at the same time one of the most unsatisfactory class of cases in their results.

The displacement of the thigh-bone in these cases of which I am now speaking is always consecutive, following some local inflammatory or general constitutional disease, the progress of which, if not arrested, terminates in the destruction of the ligaments of the joint, and often of the substance of the bones themselves.

It is not my intention to enter at any length into the description of the nature and symptoms of disease of the hip, but to confine myself to the after effects, which are generally those I am now speaking of—viz. contraction of the hip forwards, in a state of flexion varying from the slightest to the extreme degree, when the knee is brought to a right angle with the body,—adduction of the limb with rotation inwards causing the knee to overhang the opposite thigh. There is very often rotation outwards when the disease has been extensive, and when the head of the bone much destroyed, or when a false acetabulum of some depth has been formed. Ankylosis is also not unfrequently met with, when the head of the femur becomes firmly united to the ilium.

The cause of the displacement of the bone in these cases of inflammatory or strumous diseases of the hip-joint is easily explained by the action of the many powerful muscles inserted into the different parts of the femur, the tendency of some of which will be to draw the thigh-bone upwards so soon as the disease has destroyed the ligaments, and thereby removed all opposition to their action. The position of flexion is explained by the powerful muscles inserted into the trochanter minor: the patient drawing the limb upwards to relieve himself of a degree of pain by relaxing the anterior portion of the capsular ligament, the limb becomes placed in this position at an early stage of the disease, some time before the dislocation is produced by the other muscles drawing the bone upwards. The amount of displacement backwards and

upwards varies, and depends in a great extent upon the amount of destruction done to the ligaments and to the bones, as well as to the muscles. There is generally more displacement upwards than backwards in these cases of consecutive dislocation from disease: it is rare to find the head of the femur in the ischiatic notch. The shortening of the whole limb, of course, depends upon the degree of retraction and flexion; and upon the latter also depends the extent to which the toe is pointed; for when the knee can be brought nearly, if not quite, in a straight position with the body, the foot can be generally placed flat upon any artificial elevation to compensate for the shortening,—such as a high boot or other substance: but when the knee hangs forward, this cannot be done.

Displacement of the Thigh-bone with Contraction forwards, from Mechanical Violence.

There are only two classes of cases to be considered under this head—viz., dislocations and fractures—in neither of which can much be done without the deformity be removed at an early period after the injury; in the former case, before the bone has formed a new socket for itself, and has accommodated itself to its new position; in the latter, before the fractured surfaces have united so as to lock the portions of bone permanently in their new position if the fracture be of a kind to admit of bony union taking place.

The deformity from dislocation upwards and backwards is such as might be expected when the position of the bone is considered: the whole limb is shortened; the leg is turned inwards; and the knee inclined over the opposite thigh; the trochanter and head of the bone are felt in the position into which they have been forced by the violence that produced the injury, which is generally more posterior and at a lower level than in the dislocation consecutive to disease of the joint. The two principal deformities produced by fractures are, the one when the neck of the bone is split through *within* the capsule, when, I believe, union never takes place;*

* None of the cases that I have myself seen or heard of fracture of the cervix femoris completely *within* the capsule, the capsule itself being said to be uninjured, have the supposed bony unions been satisfactory to me that such was the case. I have discussed this subject fully in my *Treatise on Fractures*. Digitized by Google

the other, when the trochanters are split in one or more directions, producing the wedge-like fracture of the upper end of the thigh-bone. In the former case there is seldom or never contraction in the direction of flexion, the principal deformity being increased width on the injured side, with retraction upwards of the trochanter, and generally strong eversion of the foot; the limb is, of course, shortened. In the latter case, the existence or not of contraction of the joint in a state of flexion depends upon two causes—either the position in which the fractured portions of the bone are locked at the time of the injury, and from which they cannot be or are not afterwards moved, or else by the kind of treatment that is adopted. The point I refer to in the treatment is where these wedge-like fractures are placed on the inclined plane instead of in the long splint. The shaft of bone then follows the knee, and becomes flexed forwards, while the head and neck of the bone and portion of the trochanter connected with them remain in the straight position, not moving with the shaft; union then takes place; and when the patient comes to stand upon the limb, he finds he cannot bring the knee down beyond the angle at which it was placed during the treatment. I have given a woodcut to illustrate this point more clearly, as I am convinced it is overlooked by those who advocate the inclined plane for the treatment of fractures of the femur when situated *above* the trochanter minor.

In these wedge-like fractures through the trochanter there is almost always a mass of thickening felt in the situation of the injury, caused by the portions of bone being so displaced as to greatly increase the width of this part of the bone, and producing a consequent shortening of the limb as well. There is no rule as to the direction in which the foot may turn in these cases. It will depend upon the peculiar direction

in which the shaft of the bone is locked, whether it be in a state of inversion or eversion.

Of Contraction of the Hip-joint without Displacement.

The hip-joint may become contracted from different forms of inflammatory disease without the capsule being destroyed, and where the muscles become so much accommodated to their new position from the length of time in which they have been so placed, that when the inflammation has subsided there is great difficulty, if not impossibility, to overcome the opposition they create to bring the limb into its natural position again. The joint itself may become altered in structure either internally, by deposits, or even by ankylosis occurring, or by extensive thickening of the ligaments and surrounding textures, so as to keep it in the position of flexion into which it has been placed during the existence of the disease. Rheumatic and scrofulous inflammations may produce these alterations in the joint, and leave it in a condition of permanent or temporary contraction according to the severity with which they have attacked the joint. Inflammation and irritation of remote parts may cause contraction of the hip-joint, examples of which are seen in diseases of the bones of the spine, producing either psoas abscess or irritation in the spinal marrow, or both: in the former cases the matter runs a course which locally interferes with the action of the flexor muscles—viz. the psoas and iliac muscles: in the latter the irritation may exist either directly upon some of the nerves supplying these muscles, or indirectly through the spinal marrow as, to produce a degree of contraction in them that may either take the form of mere spasm or assume the condition of permanent contraction.

Obscure causes may exist in the spine, producing paralysis of the muscles of the lower extremities generally, from which the patient partially recovers, and remains in a condition in which the flexors are more contracted than the extensors, producing contraction of the hip-joint at the same time that there may be also an increased degree of adduction of the limb by the adductor muscles being similarly affected to the flexors. An unnatural degree of spasm may also take place without any apparent cause existing, or any previous

paralysis having occurred as just referred to; but the muscles may become so much contracted as to keep the two limbs in a state of permanent flexion and adduction; and most frequently in these cases it will be found that both the legs are affected at the same time, and combined very often with contraction of the muscles of the knees and feet as well, producing partial flexion of the former, and talipes equinus of the latter, or equino varus. The deformities in these cases are dependent upon the muscles and nerves, the joints themselves being perfectly healthy. The primary cause of many of these contractions depending upon the so-called irritation of the nerves is very obscure, there being no symptoms, either local or general, existing in many cases which elucidate the nature of the malady in the smallest degree. All we can do is to combat the effects with as much success as possible, which, after all, amounts only to an *improvement* in the condition of the patient far distant from an approach to a cure.

Another cause is found in the so-called hysterical condition of the nervous system, for the contraction of the hip-joint. It is sometimes met with in young women, when the flexors of the whole extremity become spasmodically affected, in many cases to the greatest possible extent, the thigh being brought upwards against the abdomen, and the leg backwards against the thigh, till the great toe touches the buttock. At other times the knee may be affected only, without the hip, the heel being brought backwards upon the thigh, the thigh itself retaining its natural position. It more frequently happens, however, that all the joints are similarly affected, viz. the hip, knee, ankle, and toes, most of the muscles affected being the flexors.*

The last cause I have to refer to of contraction of the hip-joint without displacement exists in the congenital form of the deformity. I do not remember to have seen more than one case, and this was under the care of my colleague, Mr. Tamplin, a drawing of which he

gives in his work on deformities, with the following description:—"The thighs being flexed upon the pelvis, the knees extended, and the feet thus contracted, were kept constantly lying on the abdomen, chest, and face of the little patient; and when the leg or legs were forcibly drawn down, they returned with an elastic impulse to their contracted position." The cause he gives, no doubt, is the correct one—viz. position "in utero." The child was born with the breech presentation, and had evidently, during its uterine existence, possessed very little, if any, power of moving the lower extremities out of the position in which they presented themselves, and which position would certainly adapt it to the smallest possible space it was capable of being placed in. There was no malformation or any evidence of disease existing or having existed in the nervous system."

The rachitic deformities of the hip-joint are more apparent than real; for the alteration that takes place is in the shape of the bones external to the joint, and not in the joint itself: the hips are widened, and the trochanters thicker and larger than natural, owing to the neck of the thigh-bone being more horizontal, the trochanters themselves being larger and thicker than they ought to be. Distortion of the pelvic bones also will alter the shape and width of the hips without the joints themselves being at all affected internally.

Having made these *general* remarks upon the nature and causes of deformities about the hip-joint, I shall proceed in my next paper to consider their treatment.

[To be continued.]

WHY DOES QUACKERY FLOURISH?

"PERSONS, in this strange world, frequently have more power than either *truth* or *fact*; and consequently, the legitimacy instrumentality of a physician is oftener interrupted by the unwise and unjust intermeddling of others, than by any other agencies." This we conceive to be the kernel of the whole subject. It is not by reason that medicine can be assailed; the raging vice of the times, the itch of people to give opinions upon all possible subjects, and most especially upon those they know nothing about, that is the secret of quackery in politics and religion, as well as in medicine.—Dr. Baldwin, in *American Journal of the Medical Sciences* for July, 1850.

* There is one point, amongst others, in the nervous system yet to be elucidated—Why the action of the flexor muscles seems so generally to predominate over the extensors, whether it be in cases of spasm or paralysis. In the former the joints are always brought into a state of flexion; in the latter the extensors are generally paralysed, while the flexors remain with the power of contraction.

AN ESSAY ON
UNHEALTHY INFLAMMATIONS.

BY M. BROKE GALLWEY, Esq.

Assistant-Surgeon Royal Regiment of Artillery,
Woolwich, Kent.

[Continued from p. 501.]

ERYSIPELAS (continued).

The arguments in favour of an erysipelatous poison—The origin and underrivativur of that poison—Its existence in the atmosphere.—Its spontaneous origin in the living body.—How accounted for in traumatic erysipelas.

BUT, if we cannot demonstrate the precise nature of the poison which I believe to lie at the bottom of the disease, let us examine the grounds upon which we may deem the evidence to be strong in favour of such (a poison) being the rationale of its phenomena.*

In the first place, when blood of a perfectly healthy description (the "good blood" of Paulus Ægineta) is determined to the skin by cold, by fire, or any other simple exciting cause, we observe it to limit itself to a particular extent of surface, to carry out all its actions within that space, to invade the part deliberately and progressively, and to decline and disappear in the same orderly manner. It is quite foreign to the behaviour of "good blood" to pounce suddenly upon, and develop itself instantly in, a new part; and it is equally opposite to its nature to quit that part suddenly and to set up a similar disturbance in some distant locality. It is just as little in keeping also with its tendencies, when once in possession of a part, to transmit itself therefrom to any considerable distance by direct extension. But, where the blood is in a diseased state, it is a prominent feature in the character of such to play all these "antics," of which "good blood" will never be found to be guilty.

In the next place, the commixture of

a poison with the blood, but more particularly of an animal poison, very generally affords early evidence of its presence in the system by its visible action upon the skin; in other words, by the production of some form of rash, blotch, or pustule. I believe this to be the rule, and the absence of such the exception. Take *typhus fever* for an example;—not to speak of the "maculated" form of the disease (an eminently ataxic form of fever), nor of others distinguished by petechiæ or by a varicelliform eruption, as described in Cheyne and Barker's work on Fever (vol. i. p. 431): the ordinary typhus of this country (even when not epidemic) will discover almost always to the naked eye a state of cutis allied to that of a general efflorescence; whilst "the desquamation of the cuticle, which usually takes place when a patient is convalescent from typhus" (Graves, p. 57), bespeaks the direct violence to which the cutis has been exposed by the morbid action of the poison. In this circumstance we behold a strong confirmation of the views which seek to enrol typhus amongst the exanthemata. In those sundry instances of adynamic types of fever, wherein mucous membrane plays a prominent part in the morbid phenomena, and the pathological condition of which after death is found to be allied to what I have just spoken of as occurring on the external skin (but which M. Broussais has elevated to the dignity of true inflammation, and invested with the importance of *originating the fever*).—in these instances, I regard the increased redness and tumefaction as *consequences of the poison*, correlative with and strictly analogous to those arising out of its influence upon the skin. If such be the correct light in which to regard them, how diverting the anathema of M. Broussais, who affirms that it is "only national jealousy which prevents the English physicians from opening their eyes to the great beauty" of his first-born—the *gastro-enterite*!

I have instanced typhus fever as an illustration of the position that morbid poisons particularly impress the skin in their play upon the actions of animal life. It is almost superfluous to introduce the formal mention of the exanthemata, as further proof of the same. The single quality of segmented colour

* "Etiam in æquivoce hæc inflammationis genere, principium morbi irritamento vires vitales excitante, et vasorum dilatationem efficiantem consistit; ejusmodi irritamentum ut plurimum est humor acris, tanquam, ascrementum, morbosus."—Cullen, *Chirurgia Moderna*, vol. i. p. 219.

which attends the family at large, denotes the irritation to which some latent cause has exposed them.

Let us next call to mind the severity of the dermoid affections ensuing upon the inoculation of the system with the matter of glanders and farcy;—the scarcely less violent affection of the skin originating in dissection wounds, where the poison introduced is much concentrated, and the blood of the recipient impure;—the thousand and one skin diseases engendered by the poison of syphilis;—the direct operation of the poisons of gout and rheumatism upon the cutis, in the struggle of the system to berid itself, and throw them off;—the morbid conditions of the cutis consequent on imperfect digestion (whether the result of disease, of the bottle, or of hereditary descent), and mal-assimilation of the food, with their natural train of evils, impure chyme and chyle, and, secondarily, impure blood;—the appearances assumed by the same structure after the absorption by the lacteals of the impurities contained in several of the fish tribe;—and lastly, those arising as a consequence of the long-continued absorption of certain medicines, as, *par. ex.*, copaiba, mercury, iodine, &c., into the blood, &c. &c.; in most of which examples the behaviour of the dermoid eruption observes a general resemblance, more or less close, so that I have dwelt upon as originating in the poison of erysipelas.

Having drawn attention, thus imperfectly, to the almost* universal rule that the presence of a poison in the blood is productive of a direct and specific operation upon the skin† in its transit through the capillaries of that

emunctory* (which operation is very generally evident to the naked eye,) I throw out the suggestion, by the way, for future inquiry, whether it be not highly probable that, in those anomalous forms of the exanthemata in which the rash is absent or defective, an explanation of the departure from Nature's ordinary rule may not be found in the supposition, alluded to a little above, that the poison is seeking other channels of elimination *within*—as the kidneys in scarlatina, the mucous membrane of the intestines and bronchi in measles, typhus,† and the like? Upon such supposition we are enabled to reconcile the occasional anomaly which we meet with in those cases in which the constitutional phenomena are present, but in which the characteristic eruption is wanting:‡

ghost, recounting to Hamlet the manner of his death, is made to say:—

“Sleeping within mine orchard,
My custom always of the afternoon,
Upon my secure hour thy uncle stole
With juice of cursed hebenon in a vial,
And in the porches of mine ears did pour
The leoprous distilment; whose effect
Holds such an enmity with blood of man,
That, swift as quicksilver, it courses through
The natural gates and alleys of the body;
And, with a sudden vigour, it doth posset
And card, like eager droppings into milk,
The thin and wholesome blood: so did it mine;
And a sweet instant tetter bark'd about,
Most faster like, with vile and loathsome crust,
All my smooth body.”

* Not the least striking illustration of this fundamental principle is the fact that erysipelas is occasionally met with in the new-born infant. † Erysipelas has been found upon the skin of the new-born infant, of which we have several instances mentioned in the Medical Commentaries as having occurred in the British Lying-in Hospital. In one of these the child was born with its whole face swelled and inflamed, the left side having a true erysipelas upon it. There was likewise an inflammation on the legs, feet, and left hand; on each tibia there appeared an oblong sough, of a dark brown colour, almost livid, that on the left being very large.” Vesications ensued, and, in some places, soughs. “The disease was observed to attack the children of weakly women, and of such as were addicted to the drinking of spirituous liquors.”—Latta's Practical System of Surgery, vol. i. pp. 136-8.

† In Cheyne and Barker's work on Fever, a case is made to an epidemic typhus in Ireland occurring in recent times, wherein increased heat of surface was often absent. Such cases usually terminated ill.

‡ “One step towards future success in these inquiries will be the relinquishment of the too exclusive attention hitherto given, even by physicians themselves, to the *eruptive part* of certain maladies.” “The translation of morbid action from internal to external parts, though far from proving identity of cause, yet indicates a series of similar morbid changes and actions analogous in their nature and progress, amongst the most important in the whole history of disease. The eruption here is not itself the disorder; but one

* The almost universal rule. A striking exception occurs in the case of hydrophobia, whose origin in an animal poison is now pretty generally assented to. Dr. Todd's views in relation to the generation of a blood-poison in the family of the neuroses, to whose immediate agency he attributes their external manifestations,—*ex. gr.* the muscular phenomena in chorea, tetanus, epilepsy, delirium tremens, &c.—would, if substantiated, augment the number of exceptions which militate against the principle contended for in the text. But, although an ardent admirer of Dr. Todd's labours in this department of medicine, I do not think he has “made out a case” for the association of these diseases with a toxic origin, although eminently dependent, no doubt, upon disordered nutrition of the nervous centres.

† Shakespeare, who was very happy in his descriptions of the play of disease and of Nature upon each other, and who delighted in such conceptions, has manifested his acquaintance with this principle in the following instance. The

To offer a last, and not the least striking argument in support of the doctrine of a poisonous origin for this disease, I may advert to the fact that erysipelas, strictly so-called, is incapable of elaborating *healthy pus** or *coagulable lymph*—the natural products of healthy inflammation. That the latter is never met with in erysipelas is a marked feature of the disease, its absence giving rise, as Mr. Travers observes, to the tendency of the inflammation to *spread*. The absence of that boundary which Nature throws up to limit the range of ordinary inflammations can scarcely fail to encourage the *creeping* tendency of this.

A host of authorities has testified to the inadequacy of erysipelas to the elaboration of *pure pus*. "Nunquam in veram suppurationem abit,"† says one; "Rarissimum" est (observes another) "erysipelas in suppurationem desinere, nisi phlegmonodes, ipsum extendit;"‡ "It est rare que l'erysipele suppure,"§ a third; "It" (erysipelas) "never runs into suppuration, but only, with weakly constitutions and other concurrent circumstances, into ulceration and gangrene; in consequence of which the destruction of the surface of the body extends to the parts beneath, and there ensues, not a bounded fluctuating abscess, but an open, wide-spreading, putrid, ulcerating surface."|| "Any effusion with which erysipelas is attended is commonly thin and acrid, and not convertible into pus."¶ "The true erysipelas" (according to Macbride) "never ends in an abscess:" and Hippocrates himself, more than two thousand years ago, insisted upon the same.

In erysipelas, uncomplicated with affection of the areolar and deeper tissues beneath, a wound occurring in such disease will not engender pus, but a serous weeping is set up in the part, which is wont to last a much longer time than healthy pus would do. My

valued friend, Dr. Weatherhead, in his essay on the "Diagnosis between Erysipelas, Phlegmon, and Erythema," has quoted a striking case from Bichat, "where 'un cautère établi au bras gauche cessa de suppuré' when attacked with erysipelas, and where the erysipelas was repelled by reproducing the suppuration by an ointment made of basilicum and powdered cantharides" (p. 17). "This is a fact" (observes Dr. Weatherhead) "which goes strongly to establish the distinct natures of phlegmon and erysipelas, and tends to show that they are not convertible, that suppuration is not natural to erysipelas, and that the phlegmon present is not an extension of the erysipelatous action," (loc. cit.) The same authority informs us that, encountering himself an "infectious erysipelas of a phlegmonous type," he made an opening into the most soft and tumid parts, out of which, instead of pus, flowed serum tinged with blood.

"*True suppuration*" (says Hunter) "I believe is a consequence only of inflammation. In treating on the cause of suppuration—viz. inflammation—I hinted that there were often swellings, or thickening of parts, without the visible or common symptoms of inflammation—viz., without pain, change of colour, &c.; and I also hinted, in treating of suppuration, that there were collections of matter, somewhat similar to suppuration, which did not arise in consequence of the common inflammation. I conceive all such collections of matter to be of a scrofulous nature: they are commonly called matter or pus, and therefore I choose to contrast true suppuration with them. Although I have termed this *suppuration*, yet it has none of its true characters, any more than the swellings which are the forerunners of it have the true characters of inflammation; and, as I did not call them inflammatory, strictly speaking, I should not call this suppuration, but I have no other term expressive of it."* Hunter is here strictly speaking of scrofulous affections—"of slow swellings in the joints," "tubercles in the lungs," "the suppuration of many joints, viz., those scrofulous suppurations in the joints of the foot and hand; in the knee, called white swellings; the

only, and that not always the most critical, of the series of changes composing it."—Holland's Medical Notes and Reflections, p. 90.

* *Erysipelas strictly so-called*—i. e., before it has involved the areolar tissue and subjacent textures. Callisen remarks:—*Erysipelas idiopathicum rarissimè vel potius nunquam veram suppurationem admittit nisi phlegmona simul junctam fuerit*.—Chirurgie Hodierne, p. 219.

* Hunter's Works, "Of the Suppurative Inflammation," vol. iii. p. 419.

joint of the thigh, commonly called hip cases; the loins, called lumbar abscesses," &c. Hunter was certainly incorrect in asserting that these collections of pus (or of "sanies," as he terms them in another place) were independent of inflammatory processes; but those processes are exceedingly *low* forms of inflammation, or, as I prefer calling them, "unhealthy" forms of inflammation. Hunter, therefore, in my opinion, would have been more correct in saying that "true suppuration is a consequence only of *healthy* inflammation." "These formations of matter" (he continues), "although they do approach the skin, yet do not do it in the same manner as collections of pus." They "are always larger than they would have been if they had been either a consequence of inflammation or attended by it: this is owing to their indolence, allowing of great distension beyond the extent of the first disease, and even of their moving into other parts; whereas an abscess, in consequence of inflammation, is confined to the extent of inflammation that takes on suppuration, and its rapid progress towards the skin prevents distension, and, of course, extension, of the disease" (p. 420). How applicable are not these observations to the process of softening in erysipelas,—bearing in mind that Hunter was certainly in error in disconnecting the sanious collections in the foregoing diseases from inflammation.* "All these formations of matter not preceded by inflammation, nor a consequence of it, are, I believe, similar to each other, having in this respect one common principle very different from inflammation;" which common principle is, he says, that none of the diseases giving rise to them produce pus until exposed, and that none of them terminate in a disposition to *heal*, which is always the case where true suppuration arises,—Mr. Hunter having considered inflammation always a salutary and never a diseased action. Without subscribing entirely to this position, I will add, from myself, that they certainly do

all possess "one common principle"—viz., *that of having their origin in the circulation of a poison in the blood*; and that it is to the presence of that poison that they are indebted for their inability to elaborate healthy pus. In this category I beg to be understood as including erysipelas in the most unconditional sense. Indeed, Hunter himself admits (p. 454), in his chapter on Pus, that there is something peculiar and unhealthy in the suppuration of erysipelas.*

Whether the same series of physical and vital changes occurs in the capillaries of the skin in erysipelas and in those inflammatory conditions of this structure allied to it, which *set in suddenly, and as suddenly take their departure*, as is known to characterise them in true inflammation, is too large a question to be discussed or decided in this place; but I acknowledge that I have my doubts upon the subject. We know that in true (healthy) inflammation it is not *until after a certain lapse of time* that the dilated capillaries become obstructed, and suffer the liquors sanguinis to exude through their walls. Nor, is it consistent with what we know of or see in this process, that such obstruction should suddenly be removed, and the enfeebled and dilated vessels as suddenly regain their natural calibre and tone; and in ordinary inflammation we are acquainted with no examples of such "*open and shut Sesame*" phenomena. But *here*, on the contrary, if the capillaries do undergo the same processes as in the case of true inflammation, it is necessary to admit this seeming paradox in Nature's operations. But, where these pseudo or unhealthy inflammations do go to the extent of

* It was not until I had written this sentence that I perused the lengthened foot-note (by the Editor of Mr. Hunter's works) at the end of the section on "Suppurative Inflammation" in the volume before me, when I was pleased to find that the able writer of it had anticipated me in the same line of strictures upon our great countryman's views of the non-inflammatory nature of the scrofulous affections alluded to.

* "To see how far the nature of sores might be ascertained from the nature of their discharge, matter from a cancerous sore has been analysed, and the result has been that such matter differs from the true pus: but this explains nothing more than what the naked eye can perceive—that it is not pus; but it will not show the specific difference between the matter from a cancer and matter from a venereal bubo where mercury has not been given, nor will it tell that one is cancer and the other is venereal! We might as well analyse the urine at different times in order to ascertain the nature of kidneys at those times!" (Hunter, vol. iii. p. 451-2.) Hunter's far-sighted sagacity has been remarkably at fault in these two instances. What would he say could he now re-appear among us, and satisfy himself that the microscope has realised both his seeming impossibilities,—that the peculiar cell of the former betrays to that instrument the existence of cancer, and the fat globule in the latter the presence of renal degeneration!

exudation, the latter consists either of serum alone, or, if of the liquor sanguinis, this is so altered in composition that it fails to coagulate into a healthy blastema, and to originate the cyto-blasts or cells of healthy inflammatory exudation. Hence, I conceive, the explanation of true pus corpuscles failing to be developed from the so-called *inflammatory* exudation of erysipelas,—or, if the cytoblasts be formed, of their being converted into abortive pus corpuscles. “Valentin, Gerber, and many others,” observes Mr. Paget,* “have not sufficiently, I think, if at all, dwelt on the probability that some pus cells are ill developed; others degenerate from a previously higher development. The many varieties of form, and the many differences of the conditions in which they occur, may be thus explained. I think, too, that the characters of *degeneracy* or imperfect development in the liquor puris have been too much overlooked.”

But I have said that the erysipelatous inflammation is incapable of elaborating *coagulable lymph* also, as well as pus. This primary product (lymph) of the healthy inflammatory process has no existence in the progress of the disease which we have now in hand: the inflammatory action here, as Mr. Travers has well observed, “is in itself wholly destitute of a healthy character, forming no stage of a process necessary or intermediate to recovery;” on which account it follows that the exudation cannot become solidified or organised so as to be developed into living tissue. “In regard to the influence of the state of the blood,” observes Mr. Paget, in the lecture from which I have just quoted, “in determining the characters of an inflammatory product, Rokitsansky has happily expressed it by saying that ‘the product of the inflammation exists, at least in part, in its germ preformed in the whole blood.’ “It is not difficult to show” (adds Mr. Paget) “that a certain character is commonly impressed by the *state of the blood* on the inflammatory product from it.” And he then lays it down as “a general truth that each morbid condition of the blood is prone thereto to produce an inflammation in a certain part or tissue, and to give to

that inflammation a certain form or character” (p. 1014-16).

That neither lymph nor true pus occurs as a product of erysipelatous inflammation is the consequence, then, in my opinion, of the circulation of a poison in the blood, the presence of which produces a septic or dissolved condition of that fluid, which renders it incapable of elaborating either.* We have here an instance of the “*præcipuus alter adjunctus morbus*,”† which Morgagni explains as the cause of the *malignancy* of some fevers as distinguished from benignant ones. That we cannot afford *palpable* evidence of its existence is no more a reproach to us, than that our senses are unable to take cognizance of the exact nature and properties of the poisons of malaria or of scarlet fever. We do not, on that account, refuse our assent to the reality of *their* existence and operation; and in demanding the same latitude for an *erysipelatous poison*, we are “accountant only for as great a sin” as we are in the cases of those diseases. Upon these principles, then, and upon this reasoning, I take my stand in this matter. “Principles,” it is said, “have no modesty. A principle never rests until it has gained the victory; and it cannot be otherwise. With it, to reign is to live. If it does not reign supreme, it dies.”‡ Let this principle, too, I now contend for, reign supreme, or let it die.

In connection with the present division of our subject, a question remains to be considered which in obscurity is inferior to none of the many that attend the history of erysipelas. That question has reference to the *origin* of the poison (or poisons) the existence of which in the causation of this disease we have hitherto been considering. *Whence* the source from which it is brought into operation? Does it exist in the atmosphere at such times? and if so, is that

* We know that certain *natural* poisons will destroy the coagulating properties of the blood almost instantaneously (vide Mead on Poisons), and render it permanently fluid. “It is well known that volatile alkali salts mixed with the blood when just drawn, or rather as it runs from the vein, keep it from coagulating, and hinder it from separating into crassamentum and serum, as usual: the experiment is easy, and every one will find it true on trial” (Huxham on Fevers, p. 51).

* “On the Processes of Repair and Reproduction after Injuries.” Lecture IV. MEDICAL GAZETTE, No. 1122, July 13, 1849.

element the invariable nidus of its creation? Or, on the other hand, is it engendered within the body itself, and wholly unconnected with influences external to the same? Or, lastly, is it of a compound nature, traceable to the united agency of both sources? and if so, are we able to point out the order and sequence of their respective operations? Than this, a more difficult problem in medicine can scarcely be conceived. It has baffled the researches of the acutest thinkers, and of the most mathematical reasoners; so that I may well be excused if I confine myself to little more than an enumeration of the several difficulties which surround the inquiry.

Its atmospheric origin?—"The remote cause of erysipelas," observes a great modern authority, "must exist at all times in the atmosphere, or else the human body must possess the power, when acted on by certain predisposing causes, of spontaneously generating this peculiar poison. The doctrine, however, of the spontaneous generation of any poison is ill supported by argument, and not generally received; and, consequently, the more probable hypothesis of the remote cause of this disease is, that it is at all times diffused through the atmosphere, varying greatly in quantity or intensity; for, although the disease is at all times sporadic, yet in some years it is epidemic.*"

Supposing the particular poison now under our notice to be at all times diffused through the atmosphere, and that one man shall escape while another will succumb under its influence, according as his system shall be predisposed to disease or the contrary, is a view which at least has the merit of disembarassing the question of almost all its difficulties; and, although it may not be free from some objections, it is the doctrine, of all others perhaps, which will best dispose of the many conflicting facts connected with the question of causation in this disease. That the atmosphere cannot be thrown out of the account altogether must be allowed at once, I think, if we admit the occasional occurrence of an epidemic form of the affection. And, if we admit a certain state of the atmosphere as capable at one time of engendering the disease, it is difficult to see

how we can refuse to recognise the possible influence of that element at another. The former admission plunges us, plainly enough, into this obligation.

Its origin by spontaneous generation?—The strongest argument which can be advanced in opposition to the atmospheric view of this question is to be found, perhaps, in the circumstance that erysipelas will spring up in a single individual, who, as far as we are able to judge, is in possession at the time of the rudest health, and surrounded by every circumstance conducive to the preservation of that state: in a word, that the disease is as common in a sporadic as in an epidemic form—far more so, I think, to speak correctly. Now, it is all very well in such cases to berid ourselves of the difficulty by presuming a *predisposition* on the part of the affected individual to take on the disease. The fact is, that such occurrence deals a heavy blow at the very foundations of the edifice of the atmospheric philosophers! I am supposing a case now, not in which a well-fed countryman shall break his leg, or incur a scratch on his body, and erysipelas break out in that part, but in which, while going about as usual, he shall be knocked down by the disease, while those around him, under less favourable circumstances, shall escape. Oh! but, then, exclaim the atmospheric logicians, his system must have been predisposed to take on the disease! To such mode of reasoning I know of no answer but that of my uncle Toby's under the like circumstances—videlicet, to put one's hands in one's breeches pockets, and indulge in a *hillibullero*! For, it is unanswerable.

But there is yet another difficulty surrounding that view of the proximate cause of this disease which refers it to the circulation of a poison in the blood, that demands a word or two at our hands ere I take my leave of the present division of this subject. The opponents of the *toxic* rationale of erysipelas have brought forward *traumatic* cases of the disease as, in their estimation, a decisive answer to those who contend for the necessity of a poison in its causation. And it must be acknowledged that herein lies their strongest argument, and a position not easy to subvert, either by direct facts or by unobjectionable reasoning. Systematic writers on erysipelas have been remarkably silent upon this point. Mr. Tra-

* Elements of Medicine, by Dr. Robert Williams, vol. I. p. 236.

vers has touched upon it in his work on "Constitutional Irritation;" but I can not satisfy myself that he has thrown any additional light upon this obscure question. "It may be asked," says he, "how is the appearance of erysipelas in a person previously healthy, after a lapse of forty-eight hours or sooner from the infliction of an injury, to be reconciled with the statement of its constitutional origin?—Simply thus: the elements of the disease have been the immediate workings and results of the injury, or, if they have pre-existed, they have been stirred into activity by its direct effects." "That a certain morbid condition is an essential preliminary to its appearance, as to that of gangrene and tetanus, is the strongest proof that can be had of its constitutional origin." Again: "Do we not see nausea, retching; obstructed or paralysed bowels, skin, and kidneys; head-ache, loins-ache; anxiety, stupor; delirium; full and bounding, contracted and wiry pulse, all following upon an injury within the same short period? And can it be questioned that here is combustible material for the change upon the part injured, whether erysipelas or gangrene? Would it not be more wonderful if, with such commotion of the citadel, the tranquillity of the outposts was undisturbed, even without the provocation of assault?"

But we are to remember that Mr. Travers explains all, in the pathology of this disease, by irritation through *reflex nervous* action, and not through the agency of blood. If "the elements of the disease have been the immediate workings and results of the injury," they produce their irritating effects on the great nervous centre, which in its turn (and after time sufficient has been allowed for the establishment of that commotion in the system, which he details) reflects that irritation back upon the originally injured part, the violence done to which lays it particularly open to a local manifestation of the same. Upon the nervous hypothesis, then, the appearance of the disease in the injured part might perhaps be allowed to be intelligible enough.

But, as I am not disposed to admit the phenomena of erysipelas to be explicable upon reflex nervous action, except in so far as that action is subordinate to the primary agency of blood, the above exposition offers no solution

of the question we have in hand. If we premise that erysipelas can only occur in such cases as are characterized by a previously unhealthy state of the blood (a position for which I must resolutely contend—Mr. Travers himself insists on the necessity of an "unsound condition of the system" for its appearance), the spontaneous generation of the poison in that blood might, it is conceivable enough, be developed in the injured parts the nervous actions of which had been done a violence to, or in some way been modified by the lesion. A little thing, under such commotion, might stir up the already existing poison to reflect or develop itself in the part. In no other way than through its spontaneous generation in the body can I conceive a poison to explain the occurrence of erysipelas in an injured part. And I confess that I think there are more arguments in favour of the possible generation of such in the humors than is assented to by Dr. Robert Williams.* We talk of the liability of persons with an *unhealthy state of body* to develop certain disorders. But in what does this unhealthy state of body consist, but in the decomposition of the elements of their blood, and in the consequent escape or generation of poisonous materials or gases? A medical student shall dissect and pore over his midnight lamp for twenty out of the twenty-four hours, and this through a period of six months consecutively. At the commencement of that period he might have wounded himself in the prosecution of the former occupation, again and again, with *impunity*; but, *at its close*, the case is quite altered; the prick of a needle will now engender diffuse inflammation of the integuments or of the areolar tissue, and such accident shall go hard with his life. And why?—Because long confinement, the absence of air and exercise to oxygenate and purify the blood, &c. &c. have disturbed the affinity between its several elements, and given rise to new compounds ungenial and unhealthy to the living system: in a word, to the generation of the so-called poisons.

That the blood is liable to undergo great alterations in its constitution, as well from an excess in some of its com-

* In connection with this question the reader is referred for many valuable remarks to the latter part of Mr. Simon's last lecture on "General Pathology," lately published in the pages of the *Lancet*.

ponent elements as from a deficiency in others, is a fact so incontrovertible, that I need not waste the time of the reader in enforcing it.* These alterations may be due to constitutional peculiarity. They are the result, again, at one time, of a vicious elaboration of the chyle and of the chyme, which in their turn elaborate a vicious blood. At another, they are due to a failure in the depurating functions of the body, and to a consequent retention in the vital fluid of materials intended to be thrown out of it. There is not the least doubt in my own mind that a *poison may thus be engendered*; or, if you will, that a state of blood may arise which, while it shall be unfit for the healthy nutrition of the body, may be capable of giving rise to erysipelas.† Such poison, in its transit through the capillary blood-vessels of the skin and mucous membranes, I suppose to be capable of occasioning an irritation that, under certain circumstances (which I do not attempt to explain), shall end in the disease under our notice. I see nothing at all far-fetched in this presumption; while it must be allowed the recommendation of sufficing to explain the much more frequent occurrence of erysipelas in the

debilitated constitutions of the naturally delicate, and in the broken-down ones of the dram-drinker, the Falstaffs, and of the "Slipperd Pantaloon," than in the robust and temperate.

In concluding this division of the subject, I wish to say a word or two upon what to me appears an error so universally fallen into by systematic writers, that it has come to be received as an acknowledged tenet in our articles of faith. I allude to the prevalence of parading forth certain *consequences* of the general pervasion of organs by a poison, as *salient points in the symptomatology and causation of the disease*. In the present instance, I will allude only to the derangements in the *hepatic* functions in the course of erysipelas, (to which our best writers are in the habit of inviting attention,) as an argument illustrative of the *influence of the liver upon the disease*. I would refer the reader to Dr. Stevens's work on the Blood for some very judicious observations upon this fallacy of physis and physicians.

[To be continued.]

ON THE USE OF CHLORINE FOR PREVENTING THE TRANSMISSION OF THE POISON OF PUERPERAL FEVER.

DR. SEMELWEIS has traced the great prevalence and mortality of puerperal fever in some of the obstetric wards of the Vienna Hospital, to the transmission of cadaveric poison from the hands of the male accoucheurs. The precaution of always washing the hands in solutions of chlorine, before making an examination, has been attended with the most marked success in arresting the occurrence of the disease. Thus the mortality, which was 9.50 per cent. in 1840, 8.44 in 1841, 16.98 in 1842, 9.57 in 1843, 8.91 in 1844, 7.40 in 1845, 13.68 in 1846, fell to 5.21 in 1847, and to 1.27 in 1848, the two years in which this precaution was first introduced.

The patients having been attended in two departments, in the one by medical men, and in the other by midwives, the mortality among the latter had been thirty-two, while it was six hundred out of the same number of cases under the care of the former. The same relative mortality attended a change of place, and was attributed to the circumstance of post-mortem examinations having been made by the male accoucheurs.—*Gazette Médicale*. x

* I may take this opportunity of explaining that it was in this sense that I intended to be understood when associating *chlorosis with a poison* in another part of this essay.

† "The causes of this malady," says Dr. Copland, "are frequently the same as those of low forms of fever, catarrh, and rheumatism; for, like them, it generally proceeds from peculiar states and vicissitudes of weather and of the atmosphere, especially cold, moist, miasmatic, and foul conditions of the air, acting upon a system already disposed to their influence by depression of vital power, or by the accumulation of morbid or effete matters in the circulation, owing to defective action of the excreting organs, to unwholesome diet and regimen, or to prolonged disorder of the prime viæ."—*Dict. of Medicine*, vol. i. p. 819. And, again, in another place, "Sir A. Carlisle says, that 'it is a humoral and constitutional inflammation occasioned by alimentary crudities,' and attended by an excess of acid in the fluids. That it is a humoral and constitutional inflammation is very generally admitted, and that alimentary crudities often precede and attend, it is also evident. I conceive, however, that not only a vitiated state of the chyme and chyle, proceeding from weak digestive power, or unwholesome and indigestible food, and vitiating the circulating fluids, but also the absorption of morbid effluvia, and the retention of effete matters in the blood owing to impeded excretion, either by the skin, the liver, the kidneys, the mucous surfaces, or the uterus: in short, that a morbid condition of the fluids, arising either from the passage into them of contaminating materials, or the retention in them of effete elements that are constantly being excreted by the various excretories, are the principal changes productive of this disease" (p. 287).

MEDICAL GAZETTE.

FRIDAY, OCTOBER 11, 1860.

THE dispute which has so long existed between Assurance Offices and Medical Practitioners, respecting the payment of a fee for filling up the usual certificate of the health of a person, has been recently turned into a question of law in the County Court of Colchester. The profession is, we consider, greatly indebted to Mr. S. A. Philbrick, a surgeon of that town, for procuring a decision on a subject which has created so much discussion; and although this decision is, in one sense, not so favourable as we might have anticipated, it fixes the law on a clear basis, and shows how, in future cases, a man may place himself in a position either to secure compensation, or entirely discharge himself of the trouble and responsibility of filling up these assurance-certificates. The case to which we refer is that of *PHILBRICK v. WHEATHAM*: it was tried in the County Court of Colchester on the 2d instant. As the particulars cannot fail to interest our readers, we subjoin a full abstract of the proceedings:—

"Defendant was sued as one of the Directors of the *National Provident Institution*, for the fee of one guinea, for furnishing particulars as to the health of a party proposing to assure his life. Mr. Hardwick (of the firm of Davidson and Hardwick, London) was retained for the Company; Mr. F. B. Philbrick appeared for the plaintiff, and observed that, although the action was brought for a small amount, it involved a question of some importance to the profession, as well as to the Society represented by the defendant. He then explained that, on the 6th of August, plaintiff received a circular letter from Mr. Marsh, secretary to the National Provident Institution, stating that, 'reference having been made to him' (Mr. Philbrick) as his medical attendant, in a proposal for a

life policy by Mr. Jas. Harwood, the Board requested that he would favour them with answers to the questions given in the document. It further stated that communications of this nature were considered as strictly confidential; and a request was added in writing that the information should be forwarded forthwith, so that the proposal might be considered and decided upon at the next Board-day. The certificate was sent up on the 8th, with a note charging the fee of a guinea; and, on the 10th, the plaintiff received a letter from Mr. Marsh, stating that it was not the practice of the office to pay fees to the medical attendants of assurers. Some correspondence on the subject not resulting in payment of the demand, the plaintiff had thought it right to avail himself of the assistance of the County Court for trying the question. The case occupied a considerable time, and the law applicable to it was the subject of a lengthened argument between His Honour, Mr. Philbrick, and Mr. Hardwick.

"The plaintiff, in his evidence, said that for some years he had furnished similar certificates to the office in question without charge: life assurance was not then so prevalent as to make the practice a burden to the profession; but since these applications had become so frequent, he had refused to supply the information without payment. He mentioned two instances in which he had actually received payment through Mr. Hayward, the Society's agent in Colchester—in December, 1848, as to the health of Mr. N. Cobb; and in the spring of this year, as to Mr. Linnett Bibby. In cross-examination he admitted that in the latter case Mr. Hayward had told him that the money came from the party effecting the assurance; but there was no such intimation in the case of Mr. Cobb: had heard Mr. Hayward say in conversation that offices did not pay these fees, but he had added the hope that he (Mr. Philbrick) would make them. Mr. Philbrick was about to call Mr. Waylen as to the reasonableness of the fee, but Mr. Hardwick said he should raise no question as to the amount: if the Society were bound to pay anything, they were willing to pay the full fee.

"The defence relied upon was in brief that the party being desirous of insuring his life—as it was one of the requisites

to enable him to do so, that he should refer to his medical practitioner—the *onus* of payment was upon the assurer, and not upon the Society. At the suggestion of the Judge, Mr. Hayward, the agent, was examined, and stated that when he applied to Mr. Philbrick about the first case he had mentioned, Mr. Philbrick said he had had so many similar applications as to Mr. Cobb, that he should decline furnishing a certificate without a guinea fee: he told Mr. Philbrick that the Society did not pay those fees, but that he would see the parties proposing to assure; and subsequently, by their authority, he paid Mr. Philbrick the guinea, explaining at the same time that it did not come from the office. In Bibby's case the transaction was similar. In answer to the Judge, Mr. Hayward said Mr. Philbrick had repeatedly told him he would not furnish any more certificates without a fee; but he had never said that *in case of applications to him he should hold the Society liable*: believed this was the first circular sent to Mr. Philbrick direct from the secretary; those which had been furnished gratuitously had all come from himself as agent.

“Mr. PHILBRICK submitted that the last answer was a very material one to the plaintiff's case, as showing a *new mode of application* to him after he had declined to furnish more certificates without payment. He also urged that upon the face of the letter itself, the agreement was between the office and the plaintiff; for he did not see how the letter could be construed otherwise than as a request from the office to perform certain services on their account.

“His Honour said, if the letter had stood alone, and this had been the *first transaction* of the kind between Mr. Philbrick and the office, he thought they would have been liable, and must have paid him; but now, as it appeared to him, the whole depended upon what had previously taken place. Of course Mr. Philbrick was not bound to continue furnishing certificates gratuitously, but he was of opinion that *he could not claim payment without previous notice*. Judgment for the defendant.—Mr. HARDWICK said he should make no application for costs, which, his Honour remarked, was a very liberal course. Many of the medical gentlemen of the

town were in Court during the trial, which appeared to excite considerable interest.”

The decision appears to have been fair and equitable. As no notice had been given to the Assurance office that certificates would in future be charged, and they had hitherto been given without charge, or, as alleged in evidence in two instances quoted, the payments had been made, not by the office, but by the insured,—it does not appear that any other judgment could have been delivered than that above recorded.

We therefore learn from the result of this case, that a medical practitioner who has already furnished certificates to an Office without payment, cannot legally claim payment for any new case unless he has given previous notice of his intention to make such a claim. The fact of the application for a certificate coming from another person, but still acting on the part of the Office, does not in any way affect the question. If, however, an Office should for the first time make an application to a practitioner, he can demand, and we apprehend recover, payment in a County Court for the important service thus rendered. The party making the application (*i. e.*, the Office) will be liable in law for a fair and reasonable remuneration. If, as they say, it is not their practice to pay such fees, and the service is really rendered to the insured person and not to the Company, this will be no defence, because, according to English law, as it is at present administered, a man who takes upon himself to give an order for an article, whether for an Insurance certificate or an arm-chair, must pay the party supplying it; and if, as it is cunningly alleged, the service is really rendered to another, then the party ordering the article has his separate remedy by action against that individual. Insurance Offices cannot benefit as principals, and evade

their responsibility under the pretence of being agents.

We do not doubt, after this decision that there will be another move on the chess-board on the part of the Offices; but if the members of the profession show the same spirit as Mr. Philbrick, it can only end in check-mate! On applying to a practitioner for the first time, or to one who has already supplied gratuitous certificates, but has since given notice that in any future case he will require a fee, it is most probable that the letter of application from the Office will contain a small printed line at the foot, to the following effect:—"N.B. It is expected that this certificate will be filled up and forwarded by Mr. — *gratuitously*. This Company does not pay fees for medical certificates." A practitioner will, however, be then placed on his guard. Unless a stamped envelope for returning it be enclosed, he should take no more notice of the application than he would of the well-known circulars of the Austrian Lottery agents, who promise the chance of a duchy with its title and appurtenances, on the purchase of a ticket at the cost of a few rix dollars. Both parties attempt to extort something for nothing, and the application should be treated accordingly. Let it be duly considered that a man who henceforth grants an insurance certificate, except in the case of a brother practitioner, without receiving a fee from the person who applies for the document, we care not whether it be the Office or the insured, is inflicting a gross injury on the profession, and retarding the settlement of a question which is seriously affecting its rights. Insurance offices, in disputing claims, have repeatedly forced into the witness-box surgeons who have given these *gratuitous* certificates, when, in speaking the truth on oath, they have been compelled, probably to the great injury of their pro-

fessional practice, to support the case of the Office on a document alleged by them to be of a *private* nature. The gratuitous certificate writer may rest assured that its privacy is only maintained by the Company so long as it suits their pecuniary interests, and no longer. Although they have not paid a fee for it, they will not hesitate, when an opportunity occurs, of turning it to the highly useful purpose of defeating a claim for three or four thousand pounds.

With facts like these it is scarcely necessary to treat as a serious argument the plea for non-payment invariably alleged by the non-paying Companies—namely, that the certificate is for the benefit of the proposed insured. He who applies a document to his own use must be considered to derive benefit from it. The proposed insured for himself neither requires nor makes use of such a document. He is ready to pay down a premium without a certificate: the Company, on the other hand, are not prepared to take his premium until they have ascertained the probable amount of risk from his usual medical attendant. Their pecuniary interest lies in ascertaining and fixing this risk as closely as possible. They cannot determine this without the medical certificate: it is therefore contrary to fact to allege that the *insured* and *not the insurer* derives the benefit from the certificate. There can be no doubt that the insurer is equitably liable for the fee: and to put this question to the best test, the following plan might be adopted by the Companies and the profession:—Let it be understood that the person proposing to insure his life pays the medical fee—the medical certificate is clearly his property, and should pass through his hands to the Company for their *inspection* only. He who has paid for the document has acquired property in it, and has a right to keep it. This plan might not accord with the views

of Insurance Companies: but if their argument for non-payment be well-founded, on what principle can they object to the adoption of such a plan?

In the meantime, however, we most strongly protest against medical men being made the victims of a mere quibble. Valuable service is rendered by the certificate: the party who requires and retains it refers for payment to him who does *not* require or retain it. This is mere shuffling. Let insurers take lives without inquiry, or let them pay for that of which they make a beneficial use.

ANALYSIS OF THE EVACUATIONS IN CHOLERA. BY M. A. BECQUEREL.

M. BECQUEREL considers from his analysis that the choleraic evacuations consist of the serum of the blood diluted by a varying quantity of water. In this fluid is suspended coagulated albumen, the particles of which are agglomerated by mucus.

M. Becquerel notices the following facts in several analyses of the evacuations:—

1. Albumen in solution.
2. Coagulated albumen, giving the rice-water character.
3. Great abundance of albuminous particles towards the end of the disease.
4. A large quantity of chloride of sodium, almost three times as much as found in the blood.
5. Acidity of the matters vomited.

The examination of the vomited matters shows considerable resemblance between these and the evacuations.

Albuminous fluid: a portion of the albumen being in solution, and a part coagulated and suspended by mucus.

This albuminous fluid is in general neutral or slightly alkaline, and containing a considerable proportion of chloride of sodium.

The analysis of the blood gives—

Increased density of the blood and serum, more especially of the latter;

Increase in the proportion of globules;

Considerable decrease of water;

Increase of the extractive matters, chloride of sodium, and other salts, and particularly of the fatty matters, to almost threefold their usual proportion;

Slight decrease in the albumen of the serum;

Increase in the proportion of fibrine towards the termination of the case.—

L'Union Médicale.

CLINICAL LECTURE

OR

CASES OF ASCITES

(Delivered at King's College Hospital),

By R. B. TODD, M.D. F.R.S.

Physician to the Hospital.

(Reported by H. H. SALTER, B.A., Dem. Anat. K.C.L.)

LECTURE XI.

BEFORE I enter upon the proper subject of this lecture, namely, that of the form of dropsy called ascites, I must call your attention to the issue of the case of cardiac dropsy, which we discussed in the last lecture. Our patient, Baylis, did not live long after we last met. The dropsy, despite of the various remedies employed, increased, the difficulty of breathing increased, fluid was effused into the pleurae as well as into the abdomen, and he died exhausted.

This is the fate of all patients suffering from mechanical dropsy when the cause is irremediable. So long as the cardiac difficulty remains, the mechanical cause of the dropsy remains, and you have no means of obviating the accumulation of water save by establishing drains at various points, to carry off this accumulation of fluid. Hence you begin by trying to excite the kidneys and the bowels, great vascular surfaces whence large quantities of water may be carried off. The continued application of the various stimuli which the materia medica afford, renders these surfaces at length insensible to their further influence; they refuse to obey the stimulus, and cease to yield a sufficient quantity of fluid. It is then that you must have recourse to more direct means of evacuating the fluid from the areolar tissue in which it has collected. You will remember that in this case, having tried the acupuncture, we proposed to adopt Lombard's* method of a single incision in each leg. This practice was so far successful that it evacuated a good deal of fluid, and gave relief for some days; but it was tried rather too late, and after a good deal of inflammation had already been excited in the limbs by acupuncture. The case was, therefore, an unfavourable one for trying the practice.

The post-mortem examination showed effusion into both pleural cavities, and into the peritoneum. The cavity of the peri-

* Or more properly, as Dr. Gall has shown, a method as old as the time of Mead, by Lombard.

cardium was entirely obliterated; in greatest part by means of *old* adhesions, the result of old pericarditis; but by *recent* adhesions over a portion of the anterior surface of the heart, towards its left side, which you will remember was the seat of the rubbing sound, which was audible for some time after his admission into the hospital. The former attacks of pericarditis had obliterated the greatest part of the cavity of the pericardium, leaving a small portion in front, which became the seat of the recent pericarditis.

Our diagnosis was quite correct as far as regards the condition of the walls and cavities of the heart. We found dilated and hypertrophied cavities on both sides. This diagnosis was indicated by both symptoms and physical signs, and therefore we were not likely to be mistaken. But there were no unequivocal signs of valvular disease, and therefore we could form no positive opinion as regards their condition.

The post-mortem inspection showed that the primary disturbing cause of the action of the heart was the almost total obliteration of the pericardium by adhesions due to an attack of pericarditis eleven years ago. During all that time the heart had been bound by these adhesions, instead of moving freely in its proper serous cavity. Its contractions were doubtless, therefore, laboured, and the contents of its cavities were probably not always completely expelled; and hence, in time, all those cavities became dilated, and their walls hypertrophied.

The condition of the kidneys was what we expected to find: they were contracted as the result of chronic disease. The cortical portion was much wasted. Many of the tubes were filled with altered epithelium and granular matter; others with fat; and others were empty and shrunk, and folded into a fibrous tissue.

You noticed the immense effusion of water which existed in the pleural cavities, and how this water compressed the lungs, so as to solidify a considerable portion of them. Now what I wish to remark respecting this fluid is, that the effusion must have taken place within a few hours of the fatal event; for we examined him only three days before his death, and found distinct audible breathing at every part of the chest. How remarkable the obstructing cause, which could give rise to the exomose of all this fluid in so short a time!

I must now call your attention to some examples of another form of dropsy—namely, ascites, or dropsy of the peritoneum, which have lately been under our observation.

CLASS I.—The first case is that of a man named John Murray, *æt.* 55, who had been for several years a butler in a gentleman's

family. This case is especially interesting as affording an example in which the dropsy was on one occasion completely removed by the aid of internal remedies; and on a second, almost so; and in which, in consequence of the subsequent death of the patient from another cause, we had an opportunity of examining the condition of organs upon which the dropsy depended.

This patient was a stout, portly man, just such a man as you would expect a gentleman's butler to be. He stated that he had always enjoyed good health, and professed himself to be strictly temperate. This, no doubt, was true; but probably he kept the key of his master's cellar, and possibly may have thought it his duty now and then to taste his wines. He drank beer, and took no great amount of exercise; and thus the seeds of disease were slowly, and gradually, and imperceptibly sown, so that he did not observe anything wrong with him, until dropsy had already developed itself in his abdomen, which began to swell by reason of the accumulating fluid. He first noticed the swollen abdomen three months before his admission.

On Murray's admission into the hospital on the 28th of August, 1848, his abdomen was quite tense with fluid, and fluctuation was most distinctly felt. His legs, too, were cedematous. No exact information could be obtained as to the state of the liver, owing to the tension of the abdomen. There was, however, an irregular and feeble action of the heart, which led us to fear that the liver was not alone at fault in the production of the dropsy.

During the three months before his admission our patient complained only of what he called a fluttering in the region of the stomach, and a gradually increasing dyspnoea. The fluttering was doubtless a sensation caused by the irregular action of the heart.

The action of the heart consisted in a series of short systolic contractions succeeding each other at irregular intervals, and evidently of very different degrees of strength; some being felt distinctly at the pulse, others exciting no pulsation in the artery, or a very feeble one. The sounds of the heart were feeble, but uncomplicated, save by a slight bellows murmur with the first sound, as heard at the apex.

There was not much miasa with the urine; it was rather high-coloured, but did not deposit any sediment, nor did it contain albumen.

Having tried for a few days the bitartrate of potash without advantage, I determined to bring the patient under the influence of mercury, and to combine with it digitalis in small quantities, watching carefully the state of the heart, in consequence

of the weakness of that organ. He was accordingly ordered one grain of powdered digitalis, one grain of squill, and two grains of blue pill; and a few days afterwards ten grains of the strong mercurial ointment, and the same quantity of the compound iodine ointment, were ordered to be rubbed in over the region of the liver twice a day.

In the course of three weeks there was a marked diminution in the quantity of fluid in the abdomen; the kidneys were excited to very free action, so that they secreted not less than from four to five pints of urine per diem. As the mouth had become sore in about a fortnight, the pill was ordered to be taken only once a day, and the frictions were continued. With these remedies was combined pressure on the abdomen by means of a bandage.

Under the influence of these remedies the patient rapidly lost all his dropsy, and went out quite cured *as regards it*, on the 19th of October, that is, in about seven weeks; the feeble and irregular action of the heart continuing much the same. The removal of the fluid enabled us to feel the liver enlarged and indurated, but without any irregularities upon its surface.

Unfortunately, soon after he left the hospital Murray was exposed to cold, and suffered an attack of bronchial catarrh; the dropsy returned, and he was re-admitted on the 11th of November, only three weeks after his discharge. Upon his re-admission we had recourse to the same treatment as that previously adopted, with the same beneficial effects. We again applied the iodine, mercury, and pressure: and in addition to this we gave him taraxacum, with manifest advantage. All his symptoms had improved, and the ascites had almost disappeared, when he was exposed to the contagion of erysipelas, at that time raging with great virulence in the ward. He vomited several times and shivered, and had sore-throat, which was followed by an extensive bronchitis affecting the small tubes; the respiratory mucous membrane having been, I have no doubt, the seat of an erysipelatous inflammation. Under the cough, difficulty of breathing, and excessive secretion produced by this affection, he rapidly fell into a very depressed state, and died suddenly in the night.

On examining the body, we found that the liver was considerably enlarged, and Glisson's capsule was much thickened, both around and in the substance of the liver. There was great dilatation of all the cavities of the heart, especially the right; and a good deal of deposition of fat upon and among the fibres of the heart, which seemed weak and ill-nourished, giving the heart a soft flabby appearance. It is very possible, also, that these may have been fatty dege-

neration of some of the fibres; but as the heart was not examined by the microscope, we cannot speak positively upon this point. The orifices of the ventricles were both dilated, and the mitral valve was shrank and thickened at its margin, so that there can be no doubt regurgitation took place at the mitral orifice during life, which explains the bellows-sound.

In this account of symptoms and morbid appearances you have the history of a large number of cases. Either the morbid state of heart, or the chronic disease of the liver, may take precedence; or the two diseases may come on simultaneously. It is probable in this case that the liver was the first organ to go wrong; and this is indicated by the nature of the dropsy, which was mainly confined to the belly, the oedema of the lower extremities being the only dropsy referable to the heart; but this may ensue upon an ascites of long standing, even when the heart is not diseased. The heart had not yet acquired that degree of dilatation necessary to the production of extensive cardiac dropsy. The condition of this man was as follows: he had a weak fatty heart, and consequently a feeble circulation; chronic disease of the liver is established, and the course of a large portion of the blood of the body, that, namely, of the intestinal canal and the spleen, is seriously impeded. This embarrasses the heart, which, in consequence of the obstructed circulation at one point, experiences a gradual dilatation. The obstruction to the circulation in the liver determines, so to speak, the dropsy to the peritoneal cavity, and the increasing dilatation and weakness of the heart would render it general. In such cases, if the disease of the liver has not yet gone to the production of contraction of Glisson's capsule, the diet, the antiphlogistic treatment, &c. may relieve the congestion of the liver, and diminish the obstruction to the circulation, and the rest may enable the heart to recover itself somewhat; the state of dropsy may be removed, and the patient may, as in Murray's case, temporarily recover; but the occurrence of any new cause of disturbance of the circulation, as, for example, the bronchial catarrh in his case, may renew the embarrassment of the heart, the dropsy may again be determined to the abdomen by the obstructed hepatic circulation, and all the old symptoms may return, to be again relieved by a similar plan of treatment to that at first adopted.

CASE II.—The second case to which I shall call your attention is that of Elizabeth Whiteman; this, like the other, terminated fatally, and therefore we can speak more decidedly as to the exact nature of

the diseased conditions. The patient was forty-five years of age, and had had eleven children. In this case there was much more evidence of the existence of intemperate habits than in the case of the butler, to which I have just referred. As is so often the case, however, she declared herself to be a very temperate person, but admitted that she was in the habit of taking a pint and a half of beer a day, and one or two glasses of gin. About twelve years ago, being then thirty-three years of age, she threw up a large quantity of florid blood. It is difficult to determine, at this distance of time, whether the blood was vomited or coughed up—whether it was a case of hæmatemesis or hæmoptysis. The florid colour favours the latter supposition; but although in hæmatemesis the blood is generally black, it need not be so always, for it may be thrown up at once, and then it may be as florid as if it came from the lungs. The cause of the usual dark colour of the blood in hæmatemesis is, that when hæmorrhage takes place into the stomach, the blood is apt to accumulate in that viscus for some time before it is cast up, and then it mixes and is blackened by the secretion of the stomach. In the lungs, on the contrary, it is expelled immediately it is effused. Six years afterwards, however, she appears to have expectorated a quantity of black blood; and the attack of vomiting was preceded by pain in the scrobiculus cordis, and followed by severe retching. It is evident that on this occasion the functions of the stomach were very much impaired, either primarily, or secondarily in consequence of disease of the liver. Five years ago she had a severe attack of rheumatic gout, affecting nearly all her joints; and two years afterwards she had another similar attack. About a month before her admission she began to suffer from severe attacks of retching, with excessive flatulence and spasms of the stomach,—symptoms evidently denoting great derangement of the stomach, due probably to irregularities of diet and intemperate habits. At this time she also began to pass urine of dark colour, diminished quantity, and depositing an abundant brick-dust sediment. Her abdomen began to enlarge at its lower part, and she suffered pain in the loins. Shortly afterwards her legs began to swell likewise.

On her admission we found very distinct evidence of ascites in the enlarged and fluctuating abdomen. Percussion elicited a clear tympanic sound over the region of the stomach, indicating that the organ was much distended by flatus. The patient was greatly emaciated, her skin was sallow, and there was a distinct yellow hue of the conjunctivæ. This patient also exhibited

another symptom (and it is one of great interest, and not uncommon, but which was not so clearly marked in the last case I narrated to you), in a great enlargement of the veins coursing over the abdomen—the superficial epigastric veins. You know there is a communication at one or two points between the veins contributing to form the portal vein and the systemic veins; and when the circulation through the liver becomes retarded, some of the blood of the portal system is thrown on the vena cava inferior, and through it on the superficial veins of the abdomen, which, naturally small and scarcely visible, become meandering blue lines, or even prominent vessels of considerable magnitude.

In this case, the patient being a woman, we had to diagnose between ascites and ovarian dropsy, a diagnosis by no means difficult, and for which the very simple process of percussion is generally sufficient. In ascites, the percussion sound is clear in the centre of the abdomen, and dull in the flanks; in ovarian dropsy the dullness exists over the whole extent of the tumor. But in some cases of ascites the length of the mesentery is not sufficient to allow the intestines to float to the top of the accumulated fluid; and then you will have a universal dullness similar to that in ovarian dropsy. In such a case you must resort to more indirect and collateral evidence for supplying the data of your diagnosis,—the history of the case—the mode in which the dropsy commenced; if it began on one side, and gradually extended—the presence or absence of liver disease, or of some other abdominal disease calculated to impede the portal circulation.

The symptoms did not appear in any degree to yield to the treatment which was pursued. She was mesenterialized, and various diuretic remedies administered; but the urine became less and less in quantity, she was frequently sick, and she became much weaker, and sunk gradually, apparently from exhaustion and insufficient nutrition, in a fortnight after her admission.

On the examination of the body we found the peritoneal cavity filled with a yellow serous fluid. The liver was contracted, and slightly tuberculated on its surface. The capsule of Glisson was much thickened; the thickening of the capsule causing a peculiar distinctness of the lobulation of the liver. When you consider how intimately connected the portal veins are with the capsule of Glisson, how that structure accompanies and envelopes them throughout their course to their smallest ramifications, you easily understand how its thickening and contraction must interfere with the free passage of blood through these vessels. Many of the cells of the liver were loaded

with fat, but others were quite devoid of it, as if starved. The heart was small, and the kidneys were healthy, but their blood-vessels much congested.

Comparing this second case with the first, we find ascites existing in both, but in the first connected with enlargement of the liver; in the second, with contraction of that organ. In both, Glisson's capsule was altered and thickened, and thus there existed in both the condition most necessary for the retardation of the portal circulation, on which depends the ascites. You may have enlarged liver without ascites, as in the simple fatty liver; but if Glisson's capsule be thickened and altered, then ascites is produced whether the liver be enlarged or contracted. That ascites, however, is much more untractable when the liver is contracted than when it is enlarged. Some, indeed, suppose that the contracted liver is an advanced stage of the same disease which creates enlargement of that organ; but the evidence in favour of this view appears to me to rest on very slender grounds. I know of no unequivocal evidence to prove that, in any given case, the liver has passed in succession through the stages of enlargement and contraction. A similar question arises as regards Bright's kidney,—is the enlarged mottled kidney an early stage of the contracted kidney? You are doubtless aware that there are the strongest reasons for answering this question in the negative, and that there can be little or no doubt that these two different states of kidney are essentially different diseases, both producing a common effect, namely, albuminous urine. So, also, it is highly probable that the enlarged liver, with thickened Glisson's capsule, is a different disease from the contracted liver, although both produce ascites.

CASE III.—The third case, that of Sarah Gadd, *et. 66*, differs from those I have just related, in the absence of that condition which in them was the most significant and important, and, doubtless, the cause of the dropsy—the thickening, namely, of the capsule of Glisson. On her admission there was no doubt as to the existence of ascites; but the previous symptoms were by no means urgent, and the dropsy had come on without any of its usual premonitory signs. There was no sallowness; the liver could not be felt, nor was there any symptom to give information as to its condition. There was, however, the negative evidence of the character of the urine—it contained no lithates; and this was so far favourable, as it denoted the probable absence of any severe organic hepatic disease.

This patient was under treatment for a long time. We gave her diuretics, especially bitartrate of potass; applied the iodine and mercurial ointment, and pressure. Under this treatment the urine increased in quantity, and the size of the belly diminished, but not so much so as to bring to light any enlargement of the liver, or the existence of any other tumor. In spite of this alleviation of the most prominent symptoms, the woman became gradually weaker and weaker (still passing a fair quantity of water), till the night of the 9th of February, when she died suddenly. The only particular symptom that could account for her sudden sinking was a cough that she had for a day or two before her death; but this seemed quite inadequate to such a result; at any rate, the treatment could not have pulled her down, as we were giving her citrate of iron and other tonics at the time.

You will remember that I had already expressed the opinion that no hepatic disease existed; and the suspicion that some deep-seated tumor, possibly of a cancerous nature, would be found external to the liver, compressing the portal vein or some of its principal tributaries, and thus impeding the circulation through the intestinal veins, and causing peritoneal dropsy. When I heard of her sudden death, the possibility of her having some internal cancerous disease was much more strongly impressed upon me; and when we came to examine the body, we found it to exist in much greater quantity than I had at all anticipated.

The diagnosis in this case was extremely obscure and difficult, for we had no definite symptom but the dropsy; that, by its situation, denoted an impeded abdominal circulation either within or external to the liver; but we had no sign of hepatic disease. There was sufficient evidence to show that the woman's habits were not intemperate; the kidneys performed their office sufficiently, and the urine was on the whole normal, although latterly it from time to time precipitated lithic acid in the form of grains. There was no evidence of disease of any other organ, whether abdominal or otherwise. Thus, then, we had a good deal of negative evidence; and all the positive evidence was the dropsy, and its persistence against all remedies denoting a persisting cause. The deposition of lithic acid somewhat favoured the suspicion of malignant disease, but gave no positive information.

On opening the abdomen a large quantity of a transparent somewhat viscid fluid escaped. The great omentum appeared shrivelled up, and was converted into a solid cancerous mass, which adhered closely

to the bowels and to the peritoneum, on the posterior wall of the abdomen, so that it must have pressed upon the mesenteric veins, and probably also upon the trunk of the portal vein itself, so as to cause engorgement of all that part of the venous circulation of the viscera which was on the distal side of the pressure, and thus mechanically to give rise to the effusion. There was a cyst, about the size of a small orange, attached to each ovary; and the interval between each of these cysts and the other pelvic viscera was filled by cancerous growths of the same kind, so that all these organs were capable of being removed in a mass. The cancer was doubtless peritoneal, and originated in this part of the peritoneum. The liver itself was not diseased; the capsule was a little thickened, but only superficially, and not that portion of it which penetrates into the substance of the organ.

Now here was a very interesting cause of the dropsy—mechanical impediment to the return of blood from the abdomen to the liver, while the circulation of the liver itself was not at all impeded. The difficulty is to diagnose between this particular cause and the other to which I have before referred, namely, *intrinsic* obstruction of the portal circulation by disease of the liver itself; that, in the present case I would call, for the sake of distinction, *extrinsic*. I know of no unequivocal sign of this condition but that of feeling the tumor. The cachectic aspect of the patient would doubtless excite suspicion; the deposition of lithic acid, too, in a diathesis not gouty, would also increase my fears of malignant disease;—but from these points we could merely guess, and, short of manual examination, I know of no sure foundation on which to build a diagnosis. Of course the evidence of the absence of disease in other organs is valuable; and we should be greatly aided if we could detect cancer in an abdominal or pelvic viscera; and our suspicions would be confirmed if the family history of the patient showed that cancer had existed in former members of the family.

The sudden death of the patient, as I said, excited my suspicions of cancer; and the reason it did so was, that I have known several cases of cancer end in a similar way; the patient suddenly sinks when perhaps you least expect it, and without any thing manifest to account for it. This woman, indeed, had been suffering for some days from difficult breathing, caused by the accumulation of fluid in the abdominal cavity; and this, no doubt, hastened her end. But we left her tolerably well the day of her death, and it was proposed to tap her; and I scarcely think that the distension was sufficient to explain the sudden change.

It strikes me that, in these cases, a certain quantity of cancerous matter passing suddenly into the circulation may cause a depression, and that the patient may die poisoned, just in the same manner as when the blood is contaminated by pus in purulent disease. In a particular class of puerperal cases death occurs very suddenly in this way, the patient passing from a state of almost health to death in the course of a very few hours; the source of the purulent infection being the surface of the uterus and the uterine veins.

Now here are three cases of ascites which I have thought worthy of your attention, as pointing out that that particular form of dropsy—peritoneal dropsy or ascites—has its origin in obstruction in the portal circulation, although not always in the same parts of that circulation. We see, also, how it may be associated with other forms of dropsy, either when, as in the butler's case, the heart is acting imperfectly; or when the kidney is diseased; or when, from the long continuance of the peritoneal effusion, pressure on the ascending cava impedes the return of the blood from the lower extremities.

Of the causes of ascites by far the most frequent is disease of *Gilson's* capsule, or of the liver itself. 2dly. Disease of the peritoneum is not an unfrequent cause, either chronic peritonitis, or tubercular or cancerous disease of the peritoneum; but these seldom cause extreme distension of the abdomen, unless the morbid mass presses very much on the portal vein or some of its principal tributaries. 3dly. Tubercular disease of the mesenteric glands, when the disease causes such enlargement of them as to form a tumor, which compresses the mesenteric veins. 4th. Enlargement of the spleen, too, is apt to produce ascites, but seldom, I think, to a great extent, as the spleen has an extraordinary power of adapting itself to changes in its circulation; and likewise because its position does not enable it when enlarged to exercise great pressure on the other tributary veins of the porta. 5th. I have seen, also, a case in which enlarged kidney gave rise to ascites. 6th. Acute peritonitis will produce ascites; this is of a different nature from those previously mentioned, and falls more under the category of acute dropsy. The peritonitis gives rise to an undue accumulation of blood in the capillaries beneath the peritoneum, and the dropsy takes place as a consequence of this congestion or sub-inflammatory condition.

I will now call your attention to one or two conditions which may possibly be mistaken, and, indeed, have been mistaken, for ascites, the necessity of guarding against

which fallacy renders the diagnosis rather more complicated.

Sometimes we find in ovarian dropsy that there is a clear tympanitic sound over the tumor; this may be caused by the development of gas in the cyst, either through a process of decomposition of its fluid contents, or by a kind of secretion, as when the bowels generate gas, but more commonly, I think, when a communication is formed between the tumor and the bowel, and the flatus from the latter gets into the ovarian cyst. A short time ago there was an interesting example of this in the hospital. A woman having all the signs of ovarian dropsy was tapped three or four times; there was dulness all over the tumor, and there could be no doubt about the case; when suddenly the tumor became perfectly tympanitic, and, on opening the body after death, a communication was found between the ovarian cyst and the intestine, through which the flatus had escaped into it, and given rise to conditions which made the case exactly resemble ascites. If the entrance of flatus had occurred earlier in the case, the diagnosis would have been extremely difficult.

Ascites, with very tympanitic bowels, would present exactly similar signs to those present in this case.

There is another source of fallacy which may be mentioned, as it was one into which John Hunter fell. Sir Edward Home mentions that that great surgeon and physiologist once tapped a *distended bladder*, under the idea that it was a distended peritoneum. We know that patients are very apt to allow their urine to accumulate, especially when they are unable either to feel acutely, or to communicate their wants, as is often the case in fever. The only symptom of the commencement of this distension may be that the patient passes a restless night: the medical attendant, perhaps, does not look for the real cause, and by and by the bladder becomes so distended as to fill the whole abdomen. Now you can easily understand how it would be very difficult to distinguish such a state from ascites. You should always ascertain how the urine is passed; and if this is such as to leave any doubt, you should pass the catheter.

There is only one other thing that occurs to me as possibly mistakable for ascites, and that is an enormously distended stomach. To what an extent this distension may take place we had an opportunity of seeing not long ago, in a woman who died of chronic gastric disease. The stomach was so much enlarged, that it filled the whole anterior part of the abdomen, all the other hollow viscera being compressed behind and below it. Such a stomach,

filled with fluid, may produce fluctuations very analogous to those of ascites. The way to put the matter beyond doubt is to produce vomiting, and cause the ejection of all the contents of the stomach: if, then, the undulating fluid was in the stomach, the fluctuation will immediately disappear. I had an interesting case of this a little time ago in my private practice; and I ascertained the nature of the fluctuation by visiting my patient the next morning before he had taken any thing, when the fluctuation had entirely vanished.

Treatment.—You may gather from the details already given in the history of the case much respecting the proper course to be pursued in the treatment. If you can clearly make out that the ascites depends on disease of the liver and of its capsule, and if the liver be not permanently contracted, then the treatment should be directed to the reduction of the chronic inflammation which affects the capsule. With this view the use of mercury should be resorted to, and in many instances it will prove highly useful, and a free discharge of water by the kidneys will often take place simultaneously with the production of pyralism.

It is also, of course, desirable to increase the action of the kidneys by other means besides. In the cases which I have detailed to you, we used as diuretics, with variable degrees of success, broom, tassa-cum, cantharides, nitre, bitartrate of potash, lemon-juice, digitalis, squills; and these are among the best of a very uncertain class of remedies.

I also recommend your attention to the part of the treatment I have made use of with great advantage, viz. pressure on the abdomen by means of bandages and strapping. Two of the cases derived great benefit from it, especially the man; he expressed himself (and the feelings of the patient are in such a case very valuable) as much relieved.

A question often arises as to the propriety of *tapping* in ascites. The opinion that I have come to is, that the operation of tapping should be postponed as long as possible; but that that should not be until the distension is extreme. When the distension is allowed to become excessive, the danger from tapping is greatly increased; therefore, if you have tried all reasonable measures and they have failed, do not wait for extreme distension, but tap at once. The danger to be apprehended from the operation is the supervention of peritonitis, and the sinking of the patient. Now the danger of peritonitis may be very much guarded against, by keeping your patient for some time previous to, and during the operation, under the influence of opium.

Still, tapping can be regarded generally only as a palliative measure, and affords very little hope of ultimate cure: nevertheless, it is not, however, perfectly hopeless, for I can tell you of two cases of recovery in my own experience. One of the cases you may have often seen; the woman frequently comes to the hospital for other complaints. She was tapped twice, and I followed the practice I have recommended to you; but with no success. I then tapped her a third time, after which she quickly recovered, and has remained well now for five years. The other case was a man who was tapped for ascites apparently dependent on hepatic disease; he got quite well, and several years afterwards came into the hospital for another disease.

Both of these cases exhibited, to a remarkable extent, a sign to which I have already alluded as not unfrequently present in peritoneal dropsy—namely, a dilated and tortuous condition of the epigastric veins. This venous enlargement is probably compensatory, and serves to open up a new and enlarged channel for the blood which cannot be returned through the hepatic circulation. Hence I am disposed to regard great enlargement of these veins as a favourable sign; and I should be more inclined to tap where that enlargement exists than where the veins remained small.

Tapping may be performed with more hope of success when the liver is enlarged than when it is contracted; and it affords least prospect of benefit when the obstructing cause to the venous circulation is extrinsic to the liver, as when it consists of a tumor, or of chronic peritoneal disease. Upon the whole I come to this conclusion—that tapping, though a remedy not lightly to be adopted, is not one lightly to be rejected; and though in the majority of cases it does not result in an ultimate cure, yet it is not perfectly hopeless.

ASYLUM FOR IDIOTS, COLCHESTER.

DR. E. WILLIAMS, Mr. R. S. Nunn, and Mr. Tracy, have been appointed to the honorary offices of Physician, Surgeon, and Dentist, to the inmates of the above charitable Institution. Previous to these appointments, the medical superintendence of the establishment has been performed by Mr. Churchill, to whom the Board of Directors have forwarded an acknowledgment of the satisfactory manner in which he had discharged the duties of the office. It is understood that a local committee is about to be formed for managing the Colchester branch of the Institution.

Reviews.

Observations on Chronic Hydrocephalus, Acquired, Sanguineous, and Congenital; with an Account of Three Cases in which the Head was Punctured, and an Examination of that Operation. By FRANCIS BATTERSBY, M.B., T.C.D., F.R.C.S.I., Surgeon to the Dublin Institution for Diseases of Children. Pamphlet. 8vo. pp. 30. Edinburgh: Inches. 1850.

THESE "Observations" constitute a very excellent monograph on chronic hydrocephalus, pointing out the real seat of the disease, its nature, and the small success that has attended the operation of tapping the head.

Acquired chronic hydrocephalus, the author observes, is most frequently developed from the age of two years to seven. With reference to its cause, Dr. Battersby is disposed to attribute it to pressure on the veins of Galen, or on the straight sinus.

"Many authors," observes Dr. Battersby, "have considered chronic hydrocephalus as a particular form of meningitis. Even were it so,—and we are far from thinking it,—the inflammatory character of the disease is too latent, or is effaced too soon, after a certain time, for any practical advantage to follow the adoption of this opinion. It may be true in some cases; but in the greatest number the disease consists certainly in a dropsy analogous to that observed in all the serous membranes, and in the areolar tissue" (p. 5).

The seat of the disease the author points out to be the brain itself, and not the sac of the arachnoid. The several forms of the disease are distinguished by Dr. Battersby.

A very full examination of all the published cases of the operation of tapping the head is given by the author, with the following conclusion:—

"An accurate examination of ancient and modern medical works" (we think it scarcely possible to have a more accurate examination than Dr. Battersby has here made) "would very probably discover other cases; but the above authorities, along with the forty cases in Dr. West's table, give about one hundred unsuccessful cases against seven, alleged successful cases,—or, in other words, one patient in fourteen was cured by puncturing the head" (p. 29).

To arrive at this conclusion, Dr. Battersby has very minutely criticised Drs. Conquest's and West's tables, and has compared these with the results of many other recorded cases. Within his own experience the operation has been performed ten times unsuccessfully in Dublin. It is clear from the author's examination of this question that the operation holds out but very slight promise of benefit; and as it is one attended with considerable danger of inflammation, we see little inducement for its adoption, more particularly, as Dr. Battersby observes, since many unsuccessful cases are never published!

We may pronounce this pamphlet to be a very useful essay: in too many systematic treatises published, statistics are adopted without sufficient examination. We trust that future compilers will not overlook Dr. Battersby's monograph, wherein the true value of therapeutic agents, and of operative proceedings, is duly estimated.

Proceedings of Societies.*

ACADEMY OF MEDICINE, PARIS.

Sept. 24, 1850.

Vicarious Hemorrhage from the Integuments of the Face.

DR. CHRESTIEN, of Montpellier, related the following case, as in some points resembling those mentioned by M. Bousquet.*

The patient, a young lady, had never menstruated, but a sanguineous discharge had occurred for many months from the skin of the malar regions. The drops of blood, as they oozed from the surface, becoming aggregated, ran down the cheeks. If wiped away with a sponge they were quickly replaced. The quantity of blood which exuded daily was from 120 to 160 grammes (= about 4 or 5 oz. Eng). This hemorrhage had occurred at every menstrual period.

Extirpation of a Bronchocele.

M. VELPEAU related, on the part of Dr. CABARET, the following case:—

H. H., aged sixty-seven years, of a strong constitution, had always enjoyed good health until September, 1849, when he first noticed the existence of the goitre,

which increased so rapidly, that in April, 1850, it considerably impeded respiration. M. Cabaret reported that it was then of the size and shape of an ostrich egg. It was moveable above and below, but behind it was firmly attached to the deep parts. The exact limits of the tumor were traced with difficulty on account of the thickening of the surrounding areolar tissues. Pressure did not cause pain, but produced a sense of suffocation. Difficulty of breathing ensued on the slightest exertion. The voice was impaired, and deglutition was also to some extent impeded.

Various applications having been tried without any beneficial result, the removal of the tumor was undertaken at the urgent desire of the patient. Two incisions exposed the tumor, one vertical, the other transverse. The dissection of the tumor from the adjacent parts was effected by the handle of the scalpel. The carotid arteries, jugular veins, and nervous trunks, were detached by the same means. The greatest caution was required at every step. Many vessels demanded the ligature or torsion, by proceeding from below upwards every ligature placed on a considerable branch secured all its branches. The base of the tumor was found to be adherent to the thyroid and cricoid cartilages, and to the three first rings of the trachea. After its detachment only a slight oozing of blood occurred, and lasted for about two hours. During the whole time of the operation, which occupied forty-five minutes, M. Cabaret estimated that about 500 grammes (= about 15 oz. Eng.) of blood were lost. The tumor weighed 250 grammes (= nearly 8 oz. Eng). The result has been entirely successful, cicatrization having been complete by the thirty-eighth day.

M. SEDILLOT observed, with reference to this case, that he did not participate in the opinion expressed by M. Velpeau, that the publicity given to these cases would tend to encourage rash attempts at the removal of goitres. It was necessary, M. Sedillot observed, to distinguish between true bronchocele or hypertrophy of the thyroid body, and false bronchocele or cysts, partial hypertrophy, and other formations developed in its substance. The latter constitute the tumors which may be removed. M. Sedillot regarded the instance under consideration, as also that of M. Roux,* with three or four that he had himself removed, to be of this nature.

MM. ROUX and VELPEAU replied, that the introduction of these new distinctions and terms would be attended with difficulties, and inconveniences, without aiding diagnosis.

* See p. 506 of present vol.

Excision of the Astragalus.

M. GREY presented a man from whom he had, twelve years previously, removed the astragalus in consequence of its dislocation, and the impossibility of its reduction. The only trace of the operation was a hollowness in the sole of the foot, and a slight limp.

ACADEMY OF SCIENCES, PARIS.

September 23, 1850.

Staphyloraphy.

M. SÉDILLOT submitted the instruments with which he had performed staphyloraphy, and related the particulars of a case in which he had remedied, by this operation, an extensive loss of the velum palati caused by venereal ulceration.

Phænomena of Phosphene.

M. MARTINET transmitted a note in which he stated his concurrence in the view of M. Serres with reference to the diagnostic value of pressure on the globe of the eye in cases of amaurosis, and at the same time claimed priority of the introduction of this means of diagnosis, having pointed it out so far back as 1846.

Ligature of the Common Iliac Artery.

M. CHASSAIGNAC stated that he had recently performed the operation of tying the common iliac artery in a man forty-nine years of age, from the inner aspect of whose thigh he had to remove a cancerous tumor, which penetrated the pelvis by the obturator foramen. The object of tying the common iliac artery was to prevent the fatal hæmorrhage which would inevitably have attended the complete removal of the tumor. This was effected with very slight loss of blood, notwithstanding that several branches of the internal iliac and profunda arteries were divided. The patient, however, died on the following day. M. Chassaignac regarded the operation as perfectly successful, so far as the ligature of the common iliac artery was concerned, and added, that according to the best surgical works this operation has not before been practised in France.

MAGNESIA AN ANTIDOTE FOR ARSENIC.

M. LUCAS, of Beauvais, states, that in as many as nine cases of poisoning with arsenic, he has found calcined magnesia arrest the symptoms of poisoning, and remove its effects.—*Journal de Chimie Médicale*. x

Correspondence.

TESTIMONIALS TO MEDICAL MEN.

SIR,—In your last number an anonymous correspondent, dating from Bath, writing on the subject of testimonials, makes the following observations—"It has appeared to me that on several occasions, the committees authorised to decide upon the form or kind of testimonial have erred, and instead of conferring an honour and benefit upon the individual or his family, have rather taken advantage of a good name to promote some local improvement, or to serve some body of men." "In the instance of Sir Benjamin Brodie, the subscriptions of his friends and admirers were diverted to the founding of a medal for the students of St. George's Hospital; the effect being to benefit the medical staff of the hospital, rather than to gratify and honour Sir Benjamin, by presenting to him a testimonial to be handed with his title as an heirloom to his family."

As the statement with regard to "the Brodie Medal" is *entirely* untrue, I feel called upon, in justice to "the Brodie Testimonial Committee," to which I had the honour to be Secretary, to inform you that the subscriptions have not in *any way* been diverted from the original intentions of the subscribers. A gold medal, and the dye from which it was struck, were presented to Sir Benjamin Brodie, and it was left to him to do with them what he might think right; and they still remain his property; neither have the medical staff, or the students of St. George's Hospital, been benefited in *any way* by "the Brodie Testimonial," as your correspondent has asserted.—I am, sir,

Your obedient servant,

CHARLES HAWKINS.

Savile Row, Oct. 1, 1850.

* * It is evident, from Mr. Hawkins's statement, that our correspondent M.D. has been misinformed respecting the Brodie testimonial. We cannot admit that his letter displays any mischievous intention. He entertains an opinion, no doubt shared by many, that portraits and medals are not in all cases the most substantial or the most appropriate testimonials to be presented to professional men. He has been unfortunate in one of the illustrations of his argument; but we consider it far better that a statement, if unfounded, should be authoritatively contradicted, than that it should be allowed to obtain credence by private circulation.

We shall only remark, in conclusion, that the letter of M. D. was published in the Provincial Medical Journal of Oct. 2d.

Medical Intelligence.

PURIFICATION OF WATER BY ANIMALS AND VEGETABLES—BALANCE OF ORGANIC LIFE.

MR. WARRINGTON has for a year past kept twelve gallons of water in a state of admirably balanced purity by the action of two gold fish, six water-snails, and two or three specimens of the elegant aquatic plant known as *Valisneria spiralis*. Before the water-snails were introduced, the decayed leaves of the *Valisneria* caused a growth of slimy mucus, which made the water turbid, and threatened to destroy both plants and fish. But, under the improved arrangement, the slime, as fast as it is engendered, is consumed by the water-snails, which re-produce it (i. e. the slime) in the shape of young snails, whose tender bodies again furnish a succulent food to the fish; while the *Valisneria* plants absorb the carbonic acid excreted by the respiration of their companions, fixing the carbon in their growing stems and luxuriant blossoms, and returning the oxygen (during sunshine, in visible bubble streams) for the respiration of the snails and the fish. The spectacle of perfect equilibrium thus simply maintained between animal and vegetable, and inorganic activity, is certainly striking and beautiful; and experiment alone can determine how far such means may be made available hereafter on a larger scale for keeping tanked water clear and sweet.—*Quarterly Review*, September.

. This is a most ingenious application of the "happy family" principle to an important purpose. The suggestion here thrown out by the *Quarterly Reviewer* really well worthy of the attention of the Board of Health. With a sufficient number of gold-fish and water-snails, their scheme of supplying the great metropolis with rain-water from Bagshot Heath, at the rate of forty millions of gallons per day, would be perfect. According to the above experiment, one gold-fish and three water-snails have an organic purifying power sufficient to keep in a proper condition for dietetic, domestic, and manufacturing purposes, six gallons of water. Those who object to aquatic scavengers when seen through a microscope on a small scale, will probably have no objection to the general employment, by the Board of Health, of visible gold-fish and water-snails! We regret to break into this organic circle, and to suggest a doubt respecting the existence of the equilibrium alleged to be maintained by these living filtering machines: but we are compelled to ask—Do the gold-fish and water-snails impart nothing to the water

but carbonic acid? Do the excreta of these animals consist of this gas, and of nothing else? If so, it is a very curious fact in physiology: if not, something in addition to the *Valisneria* would be required for the purification of the water.

FEMALE OBSTETRICIANS.

At the Stippling Court of Justiciary, on the 3rd inst., a female medical practitioner was sentenced to ten years' transportation for inflicting injuries upon a pregnant woman, which terminated in her death.

LICENTIATES OF THE ROYAL COLLEGE OF PHYSICIANS.

At the usual quarterly meeting of the Comitia Majora, held on Monday, September 30, Dr. Peacock, Finsbury Circus, was admitted a fellow. The following gentlemen were admitted licentiates of the College:—Dr. Steavenson, Heighington, Darlington; Dr. Ogle, Hertford Street, Mayfair; Dr. Tanner, Charlotte Street, Bedford Square; Dr. Kirkes, St. Bartholomew's Hospital; Dr. Frassanges, the Mauritius. Also, Dr. Bullock, Congleton, Cheshire; and Dr. Hoggan, R.N., were admitted extra licentiates.

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 4th inst.:—Messrs. G. Simpson—J. Hogg—E. Simpson—T. B. H. Wood—H. G. King—E. Whitchurch—J. Wilson—J. H. Hammond—H. Thompson.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 3rd October, 1850:—Peter Pennell, Canterbury—William Gillibrand, Chorley, Lancashire—Robert Settle, Lancashire—John Darwen, Birmingham—Frederic Foster Andrews, Lynn Regis—Jonathan Hutchinson, Jun., Selby, Yorkshire—Edgar Sheppard, Enfield.

OBITUARY.

On the 30th ult., Mr. Robert Grubb, Surgeon, of Dalston, aged 55.

On the 5th inst., at Worcester, James Swift, Esq., surgeon, R.N., aged 76, last surviving son of the Rev. James Swift, M.A., of Worcester.

CASE OF POISONING WITH ARSENIC, FOLLOWED BY SPONTANEOUS GANGRENE OF THE LOWER EXTREMITIES. BY PROFESSOR FORGET, STRASBURG.

A MAN, aged 63 years, constitution, swallowed, in about 40 minutes, a quantity of arsenic, and destroyed his health.

and constitution, swallowed, in about 40 minutes, a quantity of arsenic, and destroyed his health.

at night. About an hour afterwards frequent vomiting and purging took place. Not finding death arrive so rapidly as he had expected, the patient attempted to drown himself, but was prevented. When admitted into the hospital, nine hours after having taken the arsenic, his face was pale, he was extremely feeble, his extremities cold, the pulse small and frequent. He experienced violent pain in the abdomen, and presented other symptoms of poisoning by arsenic.

The hydrated peroxide of iron was administered, and at the same time small doses of ether, with sinapiams to the extremities. Reaction followed, and was met by leeching, &c. The symptoms of poisoning had all disappeared by the fourth day. The patient, however, complained of acute pain in his left leg, which was not altered in size or appearance: it was rather cooler than the other, and tender to pressure. Two days later the limb was in a state of gangrene below the knee. The gangrene continued to spread, and the limb was amputated above the knee ten days from the first taking the arsenic.

On the following day the patient was sensibly weaker, and gangrene had shown itself on the stump. Despite the use of every means to arrest the course of the disease, the patient sank on the tenth day after the operation. Dissection of the limb exhibited—1, mortification of all the soft parts; 2, red patches on the arteries, which were obstructed by fibrinous clots; 3, a healthy state of the veins, which contained a few coagula.

M. Forget suggests that the sphacelus in this case was, most probably, in a great degree attributable to the violent reaction which followed, and which was augmented by the brandy in which the poison had been taken.—*Gazette Médicale.* X

NOTICES TO CORRESPONDENTS.

We have particularly to request that those gentlemen who favour us with Newspapers, will either by a note or private mark indicate the article to which they wish to direct our attention. One of these rural "channels of information," sent to us last week, contains sixteen square feet of type, but there is no mark to point out the object of the writer in sending it. We regret that we have been compelled to postpone until next week the contributions of Mr. Barlow, Mr. Bate, Dr. E. J. Tilt, and Mr. Richardson, as well as the King's College Hospital Report.

Mr. Sands Cox's communication has been received.

A Lecturer on *Materia Medica*.—We shall act upon the consent of our correspondent, and forward the letter, which is written in a gentlemanly spirit, to the proper quarter. Our correspondent appears to have forgotten that the *Examiner* in question is no longer a Lecturer.

Lectures.

LECTURES

ON THE

MEDICAL JURISPRUDENCE OF
INSANITY.

Delivered in the Medical School of King's
College, Aberdeen.

BY ROBERT JAMINSON, M.D.

Lecturer on Medical Jurisprudence in the
University.

LECTURE VI.

General description of the insane state (concluded)—(c) Insane impulses (concluded)—(3) The impulse to steal—a symptom in insanity—sometimes a form of insanity—Kleptomania—distinguished from criminal theft—(4) The impulse to burn—sometimes a form of diseased mind—Pyromania—its characteristics—(5) The impulse to intoxication—medical consideration of drunkenness—legal relations of drunkenness—modifications in practice—the propensity to intoxication sometimes a disease—Dipsomania—legislation on the subject of drunkenness—(6) Morbid sexual impulses—Cythromania—(7) Unnatural impulses—(d) Physical condition of lunatics—physiognomy of the insane—the insane expression—the eye—the mouth—the ear—the complexion—the bodily physiognomy—automatic movements, &c.—odour—muscular power and endurance—insensibility to discomfort—pulse—Post-mortem appearances—Feigned insanity.

ANOTHER impulse originating from disease, which is of frequent occurrence among the insane, is the impulse to steal. I have frequently known it to be one of the earliest symptoms of insanity. A medical student, a quiet orderly fellow, suddenly took to drinking porter and stealing books, making no particular attempt to conceal either the one propensity or the other, but just as he was becoming an object of interest to the fiscal, a paroxysm of mania broke forth in full force, and the lunatic asylum was made his prison. Unmeaning theft is a common enough symptom in mania. A poor country labourer, much deformed in his person by rheumatism and hard labour in peat mooses, and of a reserved and dispirited cast of disposition, became afflicted with mania, in which was manifested neither delusion nor incoherence; indeed, there could be said to be no indications of intellectual disorder unless a more rapid flow of ideas than was

natural to him; the sole symptoms, in addition to physical disturbance, were unnatural cheerfulness, excessive talkativeness, Munchausen-like lies, and a most remarkable propensity to thieve. It did not matter what he came across; if it was small, it was pocketed; if it was ostensible, it was swallowed. When he washed himself in the morning he generally managed to finish the operation by pocketing the soap and hiding the towel. If a patient fell asleep in the airing yard or at the fireside, he was on the watch for an opportunity to plunder him. If a pair of stockings was missing he was sure to be found with two pairs on his legs.

The propensity to steal sometimes occurs as a disease uncombined with intellectual derangement, or with unnatural excitement, as in the above case; it then forms a variety of moral insanity, and has been written of under the name of *kleptomania*. Some have ascribed at this disease, but the fact of its being at times a premonitory indication and a phenomenon in maniacal delirium, forms an argument for its probable occurrence as a morbid impulse. The propensity to acquire being a natural one, constantly stimulated by the temptation of opportunity, controllable and requiring to be controlled, and the punishment of theft not being like that of homicide, extreme and irremediable, the proof of disease ought to be very clear before such a plea is allowed to have weight. Kleptomania may be presumed when the theft is the act of an individual not of a vicious character, not impelled apparently by the ordinary motives of the crime, who has hereditary predisposition to mental disease, who has formerly been insane, whose natural disposition has suddenly or gradually become changed by fever, nervous disease, injuries of the head, and by such conditions as pregnancy, or disordered menstruation, or who manifests other traces of disordered mind immediately subsequent to the act. The circumstances of the theft must also be taken into account along with the character and history of the offender. The impulse should be motiveless and irresistible. The plea will be strengthened if the articles are heterogeneous, of less trifling value than there was opportunity to seize, appropriated without guile or attempted concealment, unsuited to the wants, the condition, the tastes, the sex, of the individual, not sought to be turned to any account, unheeded after they are possessed, and not missed when returned to their owners. Lavater tells of a physician with this affection, who daily robbed his patients of such articles as spoons, scissors, keys, and watchable gear; he never made any use of these things, nor seemed to miss

them, though they were daily returned by his wife. A crate may be apparent in the nature of the articles collected: for example, an agent of the government at Vienna, we are informed by Dr. Gall, had a mania for kitchen utensils: he stole nothing else but only pots and pans, which he stowed away in a couple of rooms hired to hold the collection, and there they remained unused and unsold. I have heard of kleptomaniacs, but have never met with any in whom the mental faculties were not clearly deranged.

The next diseased impulse to which it is necessary to allude, is the *incendiary impulse*. The propensity to burn is not amongst lunatics a mischievous bent remarkably more common than other forms of destructiveness, and would not require special attention, were it not that there are grounds for believing that such an impulse may be a result of mental disease, when there is no evidence of disturbed understanding. I have occasionally known incendiary acts to be performed by the insane; the nearest approach to simple morbid impulse was in the case of a supposed criminal, in whom the fire-raising, which led to the apprehension of the individual, proved to be a forewarning of insanity. The incendiary impulse, as a variety of moral insanity, is usually termed *pyromania*, and is a disease recognized by all the best authorities in medical psychology. According to Esquirol, there are facts sufficient to prove, that certain incendiaries are moved by an instinctive impulse independent of their will, the burning being the result not of delirium, delusion, nor want of reason, but yet of a diseased motive which may be uncontrollable. A German authority, of the name of Hencke, was struck with the frequency of incendiarism by young individuals, and propounded the view, that fire-raising is in many cases to be attributed to the condition of the system at puberty, and is a disease related to the mental disorders and convulsive affections which sometimes make their appearance with the sexual development, more particularly in females. The propensity has been observed in connection with amenorrhoea, imperfect sexual character, natural imbecility of mind, epilepsy, and other nervous disorders allied to insanity. The plea of pyromania has been admitted by juries in this and other countries. For examples, I refer you to the later writers on insanity and forensic medicine. In such cases the act is motiveless, probably repeated without caution or self-protection, on various dissimilar occasions, by an individual about the age of puberty, who has a known tendency to mental disease, who is subject to some convulsive disorder, or who

in most cases is of the female sex, and labours under some disease or disturbance of function in the sexual system.

The *impulse to intoxication* is often a very prominent feature in the moral disease of lunatics. Drunkenness may be a cause, a forewarning, a complication, or a consequence, of diseased mind. Insanity is a disorder in which there is an unusual craving for stimulants of all kinds.

Medico-legal consideration of drunkenness.—The state of intoxication is not an exculpatory plea in law, nor does it constitute such a state of unsoundness of mind as to invalidate civil acts. Though it must be admitted to signify a condition in which emotion is perverted, and reason and judgment not sanely exercised, still, as it is a form of unsoundness voluntarily induced, the individual is held to be responsible for actions committed. A habit of drunkenness does not afford legal grounds for placing a person under restraint or confinement, or for interdicting him from the management of his own affairs. In Scotland, one who from habitual intoxication is liable to be imposed upon and taken advantage of, may, if he choose, inhibit himself, as it is called,—that is to say, he may put himself under trustees or curators, without whose sanction no act of his shall be valid. Any confession which an accused person may unguardedly make when in a state of intoxication may be used as evidence against himself or others, having no less weight than the voluntary disclosures which he may proffer in sober moments. No one is called upon to criminate himself; but voluntary statements, whether sober or drunken, though they may be afterwards denied, cannot be nullified as evidence by any retraction. Such is the general statement of the law; but there appear to be occasional modifications in practice. A distinction is made between partial and complete drunkenness; neither is understood to afford an exculpatory plea for criminal actions, though the latter might be with propriety urged in mitigation of punishment. Extreme intoxication, such as interferes with personal consciousness, has been held to vitiate civil acts; and, no doubt, lesser degrees would be similarly protected if the unexpected result of some accidental and unknown physical condition rendering the individual unusually sensitive to the influence of stimulants: so, also, if the state were apparent to all, and brought about by the contrivance and collusion of evil-intended parties for the special purpose of obtaining an advantage. As the law estimates the degree of culpability more from the intent than the effect of an action, it may often be of importance to plead the

state of drunkenness as lessening the presumption of malice.

The propensity to drunkenness as a morbid impulse may manifest itself independent of intellectual disorder; in such a case it constitutes the variety of moral insanity usually referred to under the name of *dipsomania*. The possibility of drunkenness being at times itself a disease, seems indicated by several circumstances. There are pathological relations between intoxication and insanity; the former sometimes passes into the latter, and more frequently still forms a predisposing or exciting cause of mental disease; the latter often unexpectedly develops the propensity to the former; a state of dipsomania suddenly appearing is not unfrequently a leading symptom in the premonitory stage of insanity. Drunkenness is often a consequence of physical organization,—an original sin of the constitution, hereditary, and partaking of the ordinary characters of hereditary disease. It is also sometimes a periodical disorder, and in all respects incompatible with the habits of the unfortunate sufferer during the intervals. Habitual drunkenness has been known to have been induced by alterations of disposition following diseases and accidental injuries of the head. Cerebral irritation from continued or intense mental emotions also occasionally compels to it. The following, with other similar cases, is narrated by Dr. Ray:—A young man, a sailor, was, for his sobriety and good conduct, elevated to the command of a ship; “but,” says the writer, “no sooner did he reach this reward of his merits, than he began to drink with all the recklessness of an old toper. As soon as he was degraded to an inferior station, no man could be more temperate; and this appearance of reform each time encouraging his friends with the hope that he had abandoned his bad habits altogether, they would restore him to the station he had lost, to be again and again forfeited by his mad propensity.”

The propensity to intoxication, when dipsomaniacal, does not follow temptation or opportunity, is contrary to habit, hereditary, conjoined with predisposition to insanity, follows some special, mental, or physical cause, is sudden, or connected with antecedent change of disposition and character, irresistible, periodical, and solitarily indulged during a lengthened unremittent paroxysm.

Enactments on this subject have varied much in different countries and times. Sometimes drunkenness has been entirely overlooked by legislators; in some cases it has been admitted as a plea in extenuation of crime: it has been punished by fines, imprisonments, and loss of civil status, and

even, under special circumstances, by death. At present, in this country, it does not appear to be sufficiently recognized either as a crime or as a disease. Legislation on the matter would be, no doubt, difficult, but not more difficult than important and useful. It would be well for society that the habitual drunkard should, in many cases, be interdicted from the control of his affairs; and it would very much lessen the labours of judicatory lords, were dipsomaniacs allowed to be put under control and restraint, subject to every inspection desirable for the prevention of abuse. Such individuals should be placed beyond the power of falling into criminal acts, or be made liable only to a mitigated punishment for crimes which legislation is careless to prevent.

Disease of the sexual impulse is not uncommon amongst the insane. It may occur as a form of moral insanity, and give rise to medico-legal difficulties. Under this head would be included the nymphomania and satyriasis of nosologists: these and such like might be comprehended, for uniformity's sake, under some such term as *cytheromania*; reserving the term *erotomania*, which has sometimes been made use of, to represent that species of monomania or of moral insanity in which the sentiment of love is insane.

Lastly might be specified unnatural impulses, which are occasionally combined with insanity of intellect. It is probable that even where this is not the case they may be attributed to disease as often as to brutality. In the words of Dr. Prichard, “they have given rise to a series of phenomena in human actions which have been considered to belong to the province of the moralist, or the enactor of penal chastisement, rather than to that of the medical philosopher. That this opinion has been founded in error,” says he, “we are fully convinced; and we doubt not that the time will come when the very names of many offences against decorum now considered as punishable crimes will be erased from the statute-book, and when persons now liable to be sentenced to the pillory or the gallows will be treated as lunatics.”

The physical condition of lunatics.—In continuation of the picture of the insane state, and in conclusion of it, I shall now advert to the physical condition of lunatics, directing your attention first to the peculiarities of the lunatic countenance.

The physiognomy of the insane.—Well established facial characteristics of disease are of great diagnostic value, affording pathognomonic indications which no endeavour of the patient can conceal, and which enable those who have profitably studied the expression of disease to some to

a fixed and correct conclusion upon a slight examination in instances where one less skilled might, after more laborious proceedings, continue in a state of uncertainty. Physiognomy as a science of character is a most vague and fanciful affair. It assumes, however, a more practical value in states of sickness, in which we do not look on the countenance as an index of disposition, but as an exponent of accidental and morbid psycho-physical sympathies. Expressions of disease, though less instinctively understood, are, when once known, more to be trusted in than expressions of thought or emotion; and when these last are not natural, but morbid, they are, being more involuntary, less calculated to mislead. The knowledge to be acquired from the appearance of the countenance is of greatest value in those temperaments in which there is most reaction between the mind and the body, and in those diseases which are most likely to induce mental anxiety and distress, or to occasion actual sympathetic disorder of the mind. "The study of the physiognomy is more essential in mental derangement," according to Dr. Burrows, "than in almost any disease. It not only guides us in doubtful cases, and instructs us to ascertain a hereditary predisposition to insanity, but also warns us of its approach." It may enable the medical jurist to come to a ready determination in cases of simulated insanity, to distinguish the approach of the disease, the presence of a lucid interval, and the validity of recovery.

What is the peculiarity in the expression of insanity? Painters and others have represented it either as simple exaggeration of emotion, or a jumble of incompatible characters. Sir Charles Bell conceives that it is a brutalized type of expression. Sir Alexander Morison, who has given much attention to the moveable physiognomy of the insane, seems to think that it is a combination of wildness, abstraction, or vacancy, with the ordinary expression of the predominating emotion. I believe that Sir Charles Bell's opinion is a correct statement; the expression of insanity is always degraded and repulsive. I refer you to the drawings and casts before you. How inferior is this excited aspect to any natural expression of mirth, self-confidence, or excited expectation! How different this suspicious look of ferocity from the coarsest natural expression of anger! Here is a monomania of pride;—distortion, not dignity, not even a ludicrous, but only an ugly caricature;—here the monomania of fear—the aspect and action of a terrified cur.

The eye is in mania an unnaturally brilliant, quick, unsettled, and projecting eye, with usually a contracted pupil. Here

is what writers term the "*oculus bovinus*"—a wide, dilated, and prominent orb, with an exposure of the whole circle of the iris. In melancholy the organ is dull, slow, downcast, and evasive. In dementia it has lost much of its natural brilliancy of expression; the pupil is dilated, the eyes droop, and the supercilia are drawn up on a low wrinkled brow, giving an appearance of stupid amazement. In cases where intemperance has been at work producing the disease, the eyes wear all along the intoxicated expression.

Many characteristic traits are to be observed about the expression of the *mouth*, especially in dementia and imbecility. It would be difficult to convey an accurate idea of them in verbal description; you will remark them in the examples before you. There is a peculiar relaxed expression very characteristic of primary or acute dementia, which contrasts very remarkably with the natural expression of the countenance as represented after recovery.

It is a curious fact, that there is a certain conformation of the external ear which is occasionally to be observed amongst the insane. To this my attention was first directed in the Hanwell Asylum by Dr. Conolly; but I believe the observation was originally made by M. Foville, who has also in addition remarked, I understand, some relations between the configuration of certain portions of the organ and the condition of the brain. These may be fanciful; but true it is that changes do take place in the shape of the ear, especially in cases of old standing: the lower portions of the pinna become enlarged, misshapen, and more vascular, while the helix and antehelix seem flattened and defective. These changes would point out some as yet but indifferently understood relationship between the condition of the cerebrum and external ear, which there are some facts to confirm: for instance, we are told by Kirby, in his "*Habits and Instincts of Animals*," that in the horse the condition of the ear in a certain particular varies with the wildness or tameness of the animal,—with its state of cerebral education in short. In the wild horse the ears lie back; in the domestic or cultivated one they are erect. Every representation of the trained animal, however ancient, as on Grecian and Egyptian sculptures, exhibits it with the ears erect; whereas in the wild horses of Tartary, and those which have run wild on the mountain plains of South America, they are uniformly recumbent.

Finally, as regards the facial appearance of the insane, you will find that in very few instances indeed is the *complexion* of a lunatic unexceptionable. In mania, when the disease is recent, the countenance will

sometimes bear the appearance of health ; but in all other forms of non-congenital mental derangement, and wherever the disorder is of any standing, the skin has either a pale and leuco-phlegmatic hue, or it is sallow, dirty, and badly coloured. A clear condition of the skin you will very seldom observe amongst lunatics. Beauty is what you will fail to discover in a lunatic hospital: the physiognomies are lined by the expression of diseased feelings, which expression is seldom such as to inspire sympathy, and never admiration; the trace of every benevolent emotion is too frequently banished from the countenance, giving place to cunning, suspicion, timidity, outrageous passions, and unworthy propensities.

The *bodily physiognomy* of lunatics, or their carriage, attitude, and gait, is also characteristic, as you will see from some of the graphic representations before you. On this point I shall no farther dilate than to say that the maniac may show during paroxysms of excitement more than his natural degree of grace in his frantic movements; the melancholic has an external appearance of slowness, shrinking, and oppression; the monomaniac with a high delusion expresses his ruling passion in a caricature of its natural language; and the positions of the imbecile and demented are usually degraded and debased.

The incurable class of the insane often exhibit a variety of *automatic movements*,—that is to say, certain habitual involuntary or semi-involuntary actions of an unvaried monotonous kind, such as an automaton might be contrived to perform. Such a symptom does not, however, of necessity indicate an incurable form of disease. These convulsive and habitual movements have received the name of *tic* from the French writers on insanity. It would be futile to attempt enumerating them, they are so various. I may mention here a curious action confined to paralytic lunatics—namely, a grinding movement of the teeth against each other, productive of a sound much louder than any you would conceive could be produced in this way. The sound is very loud, and in a room where two or three such patients are congregated together I have heard it absolutely amount to a distressing noise. It is a curious symptom, but speedily put a stop to by death. There is another phenomenon still more singular occasionally manifested by incurable lunatics, and that is rumination—a symptom which has sometimes, however, been known in dyspeptics not insane.

Insanity is frequently conjoined with a peculiar odour of the perspiration and the

breath. This fact looks odd, but many other conditions have a connected and peculiar effluvia. There is a peculiar smell which often precedes death, and which is an absolute indication of its approach—a sort of earthy odour prophetic of the church-yard. Gout and rheumatism have also a peculiar fetor; and the disease called the *pellagra*—a combination of a mental and a skin disease which occurs in Italy—is said to be distinguished by a smell like mouldy bread. The smell of mania is described as being quite *œt generis*: in some books you will find it compared to the scent of hyoseyamus in a state of fermentation. It is not confined to any of the particular forms of mental derangement. “The maniacal odour,” says Dr. Burrows, “is not always present; but I consider it a pathognomonic symptom so unerring, that if I detected it in any person I should not hesitate to pronounce him insane, even though I had no other proof of it.” Such an opinion from an authority so respectable makes this occasional symptom of mental disorder deserving of notice. A person sensitive in this way will almost always be offended by the breath of lunatic patients. All are agreed as to the insane being liable to be the subjects of a very powerful and disagreeable odour, whether special or accidental. It is remarked by all attendants, by all who have to deal with the repairing and washing of their bedding and clothes. In an old, ill-constructed, and badly ventilated asylum, I was once witness to two female attendants having their stomachs fairly upset by it in the morning, as they were engaged in unlocking the doors and opening the shutters of a gallery of sleeping apartments.

Mental alienation is a disorder related to physical debility, yet, during paroxysms of excitement, lunatics often manifest wonderful *muscular power and endurance*. Young and delicate individuals will perform almost incredible feats of strength, and continue for days in a state of unceasing motion and exertion of voice and limb, with perhaps little or no sustenance, continued want of sleep, and in spite of all the means which may be employed to depress their strength and calm the violence of their excitement. It is only, however, during a period of maniacal exaltation that the insane manifest an increase of muscular power: they are ordinarily of less than average vigour. Such an appearance of strength is in a considerable degree fallacious, being in part attributable to diminished or perverted corporeal sensibility. Indeed, when the bodily organs themselves make it clear that they have been exerted

far beyond the legitimate extent, the maddened brain will still impel them to obey its destructive mandates. You will see maniacal patients, after they have from unceasing vociferation shouted themselves into a state of inarticulate aphonia, persevering in their vocal attempts till at length they are prevented by fatal exhaustion. Epileptic lunatics have generally an augmented degree of strength during their periods of excitement. Demented patients, unless when epileptic, are usually feeble in body. When melancholics and monomaniacs exhibit much strength and endurance, the exhibition of it is attributable to blunted sensibility. In such a case they may be capable of undergoing great fatigue in obedience to their delusions; but when the will is exerted in a healthy way, in furtherance of any other object, they exhibit not merely a small capacity of attention, but a slight power of exertion and endurance.

The insane frequently manifest much insensibility to external impression, and much endurance of want of sleep, cold, hunger, and discomfort. This is an evidence of anæsthesia, not of strength or robustness. They may actually suffer physically, though they do not express themselves as sensible of suffering; the condition of insane abstraction from surrounding circumstances, and the absorption of attention by delusion, serving to deaden all natural impressions. A knowledge of such particulars is of importance for the discrimination of feigned insanity.

Dr. Rush, we are told, decided upon the insanity of a criminal from the single fact of an excited pulse. Now, as regards the pulse, it is not much to be trusted in determining mental disease. In the insane it may be found varying from 60 to 120. The most common pulse in lunatics is one which is not at all indicative of any state like acute inflammatory action: it is a soft and indistinct pulse, between 80 and 90, and easily quickened.

There are certain peculiarities in the constitution of the blood, urine, and secretions, which possess no little interest, but which we must pass over, as they would lead to a discussion upon the pathology of the disease beyond our province. I shall just briefly enumerate certain of the *post-mortem appearances* that are frequently found in the bodies of lunatics. These are, altered thickness of the scalp and calvarium; opacity, thickening, and adhesion of the meninges; effusion of serum into the subarachnoid tissue, the sac of the arachnoid, and the cavities of the ventricles; atrophy of the cerebral convolutions; redness or atrophy, and increased density, of

the vesicular nervous matter; diseases of the heart, particularly hypertrophy of the left ventricle; diseases of the lungs, particularly phthisis; diseases of the abdominal viscera, and, as a peculiarity, displacement of the colon. No definite relation has been established betwixt these or other morbid changes and special forms of mental disease. They do not constitute the disease, but are allied with it, sometimes as causes, sometimes as consequences, and sometimes as mere accidental complications. The last appearance alluded to is most common in cases of melancholia, and was first taken notice of by Esquirol. He observed that the colon, instead of pursuing its transverse course from the right to the left side of the abdominal cavity, was sometimes suddenly precipitated and tied down behind the pubis, or deflected from its course at the transverse portion in the form of an inverted arch of greater or less extent, at one time being a slight curve, at others a loop so long as to fall into the pelvis. Most of these post-mortem appearances are best marked in old cases. It often happens in recent cases, and occasionally, too, in old cases, that no pathological alterations whatever in the brain can be discovered either by the knife or the microscope. There is no mode of investigating insanity so discouraging as that by post-mortem examinations, and few have persevered very long in the attempt to elucidate its mysteries in this way.

You have now had laid before you a description of all the features which are characteristic of the insane condition—at least, all with which it appears necessary that the medical jurist need be acquainted in order to expose feigned insanity, and to give sound opinions in cases of judicial difficulty.

On the subject of *feigned insanity* I think I may venture to be very brief. I need not lay before you the objects which may lead a person to feign madness: but bear in mind that a person may be suddenly attacked with insanity under some of the ordinary circumstances which tempt persons to feign the disease. For example, the excitement accompanying the commission of a criminal deed, the remorse which may follow its execution, or the shame of discovery, might occasion a real attack of madness liable to be canvassed and dealt with as a feigned lunacy, owing to the suspicious circumstances in which it had been developed. All forms of insanity are difficult to be feigned, and easy to be detected when attempted to be simulated. The general rules for the detection of feigned disease are applicable to the detection of insanity. I need not take up your

time describing how the imposition of imbecility, maniacal excitement, fixed delusion, or morbid impulse, is to be exposed. The history of the individual, his character, the history of his crime, the aspect of his symptoms, are all available. Every circumstance mentioned in describing the lunatic condition has a practical application to the discrimination of feigned insanity. The true lunatic has peculiarities of physiognomy, attitude, action, and appearance: he has certain distinguishable and broadly marked emotional and intellectual symptoms, which would require to be long and perseveringly studied to be successfully imitated by even the most accomplished actor, and there are pathological features of madness which cannot be assumed. I do not think that there are many diseases whose subjective symptoms it would be more difficult to feign. In most instances, a feigned lunacy would be at once suspected, even by the inexperienced, and in every instance distinguished by those well acquainted with the characteristics of the disorder. Those who do not know insanity from having personally observed it seem to conceive it badly. Dramatists and writers of fiction, excellent depicitors of natural character, have not in general been very successful in their delineations of insanity.

SCHENBEIN'S RESEARCHES ON OZONE.

M. BECQUEREL has laid before the Academy of Sciences, Paris, the following experiments and observations on ozone which have been communicated to him by Dr. Schenbein:—

A supply of ozonized air may be procured by placing in a globular glass vessel of from ten to fifteen pints capacity, and accurately closed, a small quantity of water which about half covers some pieces of phosphorus about a centimetre (≈ 393 Eng. inches) in diameter. After some time, the glass vessel is to be inverted in a tub of water, so as to withdraw the pieces of phosphorus, and the ozonized air is to be agitated with water, in order to wash it thoroughly: the neck of the globe is then to be stopped with a cork which shall admit of the passage of two tubes, one to permit the admission of water, the other to allow of the exit of the ozonized air.

Under the preceding conditions, ozone is formed by the contact of the vapour of phosphorus with oxygen and aqueous vapour. It is not formed at the same temperature in dry oxygen, nor in moist pure oxygen at the ordinary pressure of the atmosphere; but its formation takes place under diminished pressure, or when the temperature is raised to 70° Fahr.

The presence of certain other gases, as hydrogen, nitrogen, or carbonic acid, have the same effect as the elevation of temperature, or the diminution of pressure.

Ozone is not formed in moist air at the freezing point, but takes place rapidly at an elevation of six or eight degrees.

Increased density of the air is opposed to the production of ozone, as also are certain gases, as olefiant gas and nitrous vapour.

When ether vapour is slowly burnt in air or in oxygen, among other products a compound of ozone and olefiant gas is formed.

By passing ozone through a tube heated to about 600° Fahr., it is completely destroyed.

Ozone is insoluble in water: it is destructive to the life of small animals when these are placed in an atmosphere strongly charged therewith: it destroys colours, also ligneous and albuminous matters: it combines chemically with chlorine, bromine, and iodine, in the presence of water, forming acids. Atmospheric air charged with ozone and exposed over lime water forms nitrate of lime.

Ozone in the nascent state, in contact with water, nitrogen, and a strong base, generally produces a nitrate of the base. A small portion of nitric acid is produced by the slow combustion of phosphorus in atmospheric air.

Ozone acts powerfully on most metals, causing them to pass into the highest degrees of oxidation: it combines directly with olefiant gas without decomposition: it destroys sulphuretted hydrogen, seleniuretted hydrogen, &c., and changes nitrous and sulphurous acids into nitric and sulphuric.

Ozone precipitates oxide of lead from alkaline solutions, or from acetate of lead: it rapidly decomposes salts of protoxide of manganese, whether solid or in solution, producing peroxides: whence it results that a strip of paper impregnated with sulphate or chloride of manganese serves as a reagent for the detection of ozone, by its becoming rapidly changed to a brown colour. The same occurs to starched paper moistened with iodide of potassium.

A solution of yellow ferrocyanuret of potassium is changed by ozone into the red cyanuret.

Ozone, according to Schenbein, is the most powerful oxydizing agent in nature: it is produced in the air by electrical changes, most abundantly in winter, especially during a fall of snow.—*Comptes Rendus*, 1850. X

Original Communications.

A SUPPLEMENT TO
SOME OBSERVATIONS ON THE
MUSCULAR CONTRACTIONS
WHICH OCCASIONALLY HAPPEN AFTER
DEATH FROM CHOLERA.

Containing a note of a case of Apoplexy, after which similar Movements were remarked.

By WM. FREDERICK BARLOW, M.R.C.S.
Resident Medical Officer to the Westminster
Hospital.

THE more attentively the subject of post-mortem contractions is considered the more worthy of study will it appear; and it is really a fit matter for astonishment that it should so slowly have attracted the thoughts of inquirers. Like every other topic actually submitted to contemplation, it amplifies as one views it; what once seemed peculiarities take another shape, and the air of strangeness which it wore at first sight fades gradually away. Phenomena gather more thickly, are more illustrative than might be imagined. If observers would but take the trouble of fairly and intelligibly recording all the facts which touch upon this interesting question, we should soon obtain a history which would do much more than repay perusal; but some have thrown away the opportunities which have occurred to them of illustrating the inquiry, or have so dimly, so superficially observed, that their remarks are of but trifling value.

In the present state of the question facts are yet acceptable. I have been indebted to Mr. Kesteven for the following particulars:—"In 1832 I attended a gentleman, aged 42 years, who died of cholera in fourteen hours. After death the muscles of the lower jaw continued to act for two hours: the jaw was not moved as in speaking, but the mouth simply opened and closed at regular intervals, which gradually lengthened. In the same body the muscles of the abdomen were observed to have a tremulous movement. The muscles of the thighs also, more particularly the sartorius, were in action; they contracted in spasmodic twitches, but not sufficiently strongly to raise the limbs, though these were slightly moved."

This is clearly to be placed amongst the most striking class of cases. The movements of the jaw remind one of what is sometimes witnessed in the heads of decapitated animals. The time of their continuance deserves particular notice. I believe that contractions of this kind endure seldom so long as two hours; but one ought to speak with deference on this point, because future inquiry may find them to be renewed after a longer period of cessation than we are now acquainted with. The form of the motions was peculiar; and they appear to have been rhythmic, or almost so, and unlike any voluntary action. I have noticed rhythmic movements in insects, from which I had removed the heads, that I think should be classed with such as these. The intervals between the movements lengthened: this circumstance probably indicated, and was caused by, diminished irritability of the muscles. The tremor of the abdominal muscles observed here has not been, so far as I know, nearly so frequently seen as that of the muscles of the legs, arms, chest, and face; for what reason I cannot tell.

Dr. Risdon Bennett some time ago informed me of a case in which the respiratory muscles seem to have been spasmodically affected after indubitable dissolution; and I refer to it on the ground that contractions of those muscles would be especially likely to delude some persons as to the fact of dissolution being absolutely real.

Amongst my own too many omissions I regret to have made no special observations as to the time of occurrence, degree, and duration of rigor mortis, in those cases wherein post-mortem movements or quiverings were seen: these points require investigation.

Inquiry as to the event of post-mortem contractions should obviously not be confined to cholera; so to restrict it would be at once to narrow and mystify the question. We need a knowledge of all the circumstances under which they occur. Some writers would imply, by the way wherein they mention them, that they have only been noticed after Asiatic cholera; but this is a mistake, and needs well pointing out, inasmuch as it might lead a person to suppose that the poison of cholera of this type, whatever it may be, or the peculiar state of blood occasioned by it, is necessary to their production.

It may reasonably enough be made a question whether similar movements do not ever happen after English or common cholera.

A fatal case of this form of disease occurred this autumn in the Westminster Hospital. It was extremely severe; the temperature was strikingly diminished; and, but for the *bitious* dejections, it might have been called Asiatic, if we may still apply that epithet to a malady, now, most unhappily, European also. The patient, a man *et. 40*, died, was laid out in the usual way, the arms being placed straight by the side. In about an hour the arms were found bent at right angles, one hand being placed upon the chest, and there was complete rigor mortis.*

There are two points of interest here: first, the early setting in of rigor mortis; secondly, the remarkable change in the position of the arms. What was the latter owing to? The most probable explanation that can be offered is, that first they were moved by muscular contraction, such as depends upon irritability, and then were fixed in their changed position by the quick supervening of rigor mortis. If this explanation be rejected, it must be attempted to account for the altered posture by referring it to the rigidity of death. Now there is nothing in the present state of our knowledge, so far as my information goes, which would justify us in so referring them. Nysten went the length of stating that "the position of the limbs always remained unchanged" by rigor mortis; and who has treated of this phenomenon more forcibly, more delicately, more beautifully than he? His authority may be cited against such a notion. Nor is there anything in the opinions of M. Sommer, as stated by Professor Müller, which would warrant the conclusion that so marked a flexion as that noticed in the case before us could be satisfactorily explained in the manner mentioned. Let me, availing myself of Dr. Baly's translation, lay the passage alluded to before the reader. M. Sommer states "that a *slight* motion takes place when the muscles become rigid. He affirms that Nysten was incorrect in stating that the position of the limbs always remains unchanged.

The lower jaw, he says, though it be separated from the upper jaw at the time of death, becomes afterwards firmly drawn up towards it. The extremities also become more strongly flexed: thus the thumb is drawn towards the palm, and even the fore-arm is a *little* bent on the arm."†

I have ventured to put two words in italics; and I think that, admitting M. Sommer to be right, and Nysten to be in error as to the point disputed, we cannot properly conclude that the flexion in the example stated was, looking well to the *degree* of it, produced by the rigidity of death. If it really were so, it is quite clear that so extreme an effect of the phenomenon is unusual.† I should have dwelt thus far upon the change of posture were it only for its physiological import; but it has also a most practical relation to medical and medico-legal inquiry; for it is very plain that such alteration of position might lead to the conclusion that a person had been pronounced dead before he really was so, to the prejudice perhaps of his medical attendant, and the discomfort of his friends, who might even imagine that some chance of saving life had, owing to ignorance or inattention, been thrown away.

It is to be regretted that the body in the case narrated was left unwatched between the time of death and that of the coming on of rigor, for it would be important to be able *certainly* to state that muscular contractions had occurred. As it is, I can merely affirm my belief that they most probably did happen, and that it will very likely be one day established that such contractions may occur after rapidly fatal English, as well as after rapidly fatal Asiatic or epidemic cholera, and that no distinction between these affections or forms of affection can be based rightly upon them.

It is to be supposed, since cases differ greatly, and also the subjects of them, that post-mortem muscular contractions may be more common in some epidemics than in others: and I have been informed that they were not so frequent in Paris during the late visitation as in a former one.

In relation to post-mortem muscular

* This case happened during my absence from town. I owe the account of it to Mr. Kidd, and notes taken by Mr. Morris.

† See Elements of Physiology, p. 890.

† I have made a few remarks on the alteration of the position of the dead in a former contribution on the Condition of the Body after Death by Cholera. See MEDICAL GAZETTE.

contractions in general there is nothing of higher importance to determine than the various circumstances under which they may happen. When are they most likely to be observed? When most likely to be observed most strikingly? What does pathology, what does experimental physiology, say respecting them? How is it that they were only first observed since cholera in a malignant form was known to us?

Dr. Dowler, whom I have referred to in previous remarks, on account of the importance of the facts he has narrated, has put on record a well-marked case wherein these contractions happened after yellow fever—a disease, it will be remembered, in which he has shown repeatedly how readily muscles may be excited to contraction after life is over by means of percussion.

What, more especially, are the forms of sudden or rapid death, for I suppose they are quite limited to such dissolutions, in which these contractions, if seen at all, would probably be found most violent and most protracted?

I have referred already to two instances of muscular quivering which were remarked on post-mortem examination: one of them was a case of tetanus. In this affection the disposition to spasm is, despite exhaustion, extreme unto the end, and there are manifestations of irritability when the general powers are too obviously declining.

I find the following passage in a case of disease of the spinal cord described by the distinguished Bellingeri:—"The spasms disappeared for a short time, and returned with greater severity, so that death appeared to have been produced by asphyxia, owing to a spasmodic action of the glottis. Immediately after death the left arm was drawn spontaneously backward."

I do not remember to have read any case of post-mortem contractions in the writings of Sir Chas. Bell, Dr. Marshall Hall, Dr. Abercrombie, and others; nor in those of some celebrated French authorities on the nervous system. Dr. Marshall Hall, as I can state from conversation with him, has never yet seen any after disease. The most distinguished surgical authorities on injuries of the brain and spinal cord make no allusion whatever to the matter. And yet some diseases and injuries of the nervous system occasionally destroy with an exceeding swiftness; the muscular system

is well, and sometimes even extraordinarily nourished at the time they surprise; the muscles must be not rarely extremely irritable at the moment of death; and there is, all things considered, a condition of the body wherein the occurrence of such movements might surely not unreasonably be expected; neither might they, one would think, be absurdly looked for after some abrupt terminations of heart affection.

It was not, however, until a short time ago that, with the exception of what happened in consequence of cholera, I observed any movements whatever after death, though I am no stranger to the aspect of the body on sudden dissolution taking place. I allude to a fatal case of Apoplexy, and will now endeavour to describe briefly some phenomena which succeeded to the last expiration.

John Reid, a well-developed man, *stat.* 41, was admitted, one day last summer, at 1 o'clock A.M., into the Westminster Hospital, under the care of Dr. Basham. He had been apparently struck by apoplexy, was completely insensible, breathed very stertorously, the circulation was languid, and he was pale and cold. The pupils, unlike what generally happens in the apoplectic, were as narrowly contracted as I have ever seen them, either in sleep or poisoning by opium. He could be made to swallow with great difficulty. Some wine, was, however, administered, and in a few hours he rallied considerably, at least so far as organic life was concerned; his breathing was less embarrassed, although still alarmingly impeded; his pulse became more vigorous and rapid, and there was a most palpable increase of animal heat, which I now regret was not measured by the thermometer. Towards evening he became obviously worse, and died at a quarter past 7 o'clock, no convulsion or spasm of the face or extremities having been noted previous to his decease.

Scarcely had he died, when the nurse who had attended on him hurried to me, and said that he was moving much as some of the patients did after death by cholera. I of course went directly to see the corpse, and found it was true enough. My attention was first attracted by motions in the feet. The toes were flexed; sometimes altogether, sometimes two, or one only, were inflexed, and the contractions varied greatly

in force. The whole foot was distinctly moved several times, but not with any great degree of violence. The tibialis anticus was in a frequent flickering action. The whole of the muscles was not affected, at least not visibly. A narrow portion only, running its whole length, was seen to act; but so fleeting was the motion, that unless the eye was fixed upon the muscles at the very time of contraction it would have eluded notice. The motions of the toes could be much more easily surveyed. They now affected one foot, now both feet simultaneously. The gastrocnemii muscles were once or twice slightly influenced. The hands were slightly moved twice or thrice; and the fingers flexed several times. The motions would pause for a while, and then be renewed, coming and going just as I have seen them after fatal cholera. I could not *exactly* discernible motions, either by flexing the limbs, or striking the muscles, or picking them. There were no motions of the face, thorax, or abdomen. The contractions were timed, and found to last *three-quarters of an hour*. They could not have been distinguished in any way from those which have been noted subsequently to cholera; and if I have seen some evidently more marked and striking after that disease than these were, I have likewise noticed others which were infinitely less so.

The surface felt extremely warm. I placed the bulb of a thermometer in the axilla *half an hour* after death, and ascertained a temperature of 104° . The body had been, judging by the touch, of an unusual heat during lifetime. I do not, therefore, mean to imply that there was any rise of heat. I do not think that there was, though it is impossible to affirm this positively.

Bodies should be watched closely and patiently after all kinds of sudden and rapid dissolution, by any one desirous of witnessing such motory phenomena as those described: experience only can determine how often search will be successful. But it must be remembered that the *most rapid* deaths, some through violence, and more in the course of nature, occur month after month, day after day; the subjects of them must often be observed more or less closely, and for a longer or shorter time after dissolution, by friends, or others, with them when they die, and yet no motions are seen in such cases at all comparable

to those which happened in this apoplexy, though there may be occasionally a faint muscular quivering or two observed, enough to attract a passing notice. Only let us imagine the vast numbers who annually perish in hospitals, infirmaries, union houses, and private dwellings, without any such remarkable movements being seen. Still, in most new inquiries, one is supplied with more abundant instances than were hoped for. This is a consequence of research. Look at the many cases of reflex action in paralytic limbs which have now been seen at one time or other. Most of them would certainly have been passed over, but for special questioning.

We have long heard of post-mortem movements happening in India. Some formerly have either treated them as fables, or not troubled themselves about them because of their occurring so far away. So with many the cholera excites no interest now. They say it is in Malta, and elsewhere, but not here; that the topic is not popular, and they will think no more of it till the disease returns. Should it again invade, there will once more appear a myriad of contributions, and the columns of journals, medical and general, will be forthwith crowded to inconvenient excess.

It can, with difficulty be supposed that the case of apoplexy which I have just sketched is the *only* instance of that affection in which these contractions have taken place, though it may be the only one in which they have been seen to any remarkable extent; and it may be conjectured that other cases of sudden or rapid destruction caused by injuries or diseases of the nervous system, or other injuries or maladies, or, perchance, by the speedy course of poisons, will, sooner or later, be found to exemplify them. It remains for future inquirers to treat the whole subject of them in its length and breadth; to note the species of death in which their supervention will be most probable; to mark accurately their periods of beginning, declining, ending; their course, their form, and what may best provoke them; to trace minutely every circumstance of interest, and to show with all clearness, fulness, and judgment, their every physiological and pathological bearing. What I have written is but a fragment.

Let me now subjoin a short state-

ment of the principal pathological changes observed after death in the preceding instance.

There was no peculiarity in the external appearance of the body, which was examined *eighteen* hours after death.

The limbs were by no means unusually rigid.

The vessels of the brain were more congested than usual, and a flattening of the convolutions was observed.

On opening the left lateral ventricle it was found completely filled with coagulated blood; the septum was broken down, and some bloody fluid, with scarcely any coagula, was observed in the fellow cavity. Some blood, too, had made its way into the fourth ventricle. The hæmorrhage seemed to have proceeded from the corpus striatum, thalamus opticus, and almost the entire portion of brain which formed the floor of the left lateral ventricle. This portion was soft, irregular, shreddy, and the blood which covered it was mixed here and there with diffuent cerebral matter. Numerous bloody points remained diffused everywhere, after water had been gently but freely poured over it. There was no marked degree of softening in any place, if we except that part of the brain which lay just immediately beneath what appeared the direct seat of the apoplexy.

The arteries at the base of the organ presented unmistakable and pretty general signs of fatty degeneration. The heart, which was, I think, to some degree enlarged, showed a marked rigor mortis, such as formerly led to the use of the erroneous term "concentric hypertrophy." The aorta was thickly studded with atheromatous or fatty deposit, and there was a considerable layer of fat upon the surface of the right ventricle. The kidneys, which lay imbedded in most abundant fat, were atrophied, and far advanced in granular degeneration. Some urine was in the bladder, which was highly albuminous.

Thinking it most likely that the muscular fibres of the heart would be to some extent in a state of fatty degeneration, though, looking to the rigid state of the organ, not far gone therein, I requested Dr. Quain to examine it microscopically; but, through accident, the heart did not reach him in a state sufficiently fresh to admit of that satisfactory scrutiny which was desirable.

Dr. Quain observes, in a letter with

which he favoured me,—"There is abundant evidence of granular fatty matter in the muscular fibres. This appearance exists throughout several parts of the heart that I have examined; but the granules are very small. The degeneration, therefore, though extensive, is not greatly advanced. It is possible that the presence of some of this matter is due to decomposition; still I feel quite satisfied, from the general appearance of the heart, that fat would have been found if the heart had been examined when fresh."*

Examinations of cases of this kind cannot, of course, be satisfactory without the microscope be used. The pathology of fatty degeneration is only to a slight extent explorable by the unaided eye. I can hardly doubt that, had the small blood-vessels of the brain been examined, we should have discovered in such degeneration of them the precursor and cause of the apoplexy. I rest this observation on a communication of Mr. Paget to the Abernethian Society, "On Fatty Degeneration of the Small Blood-vessels of the Brain, and its relation to Apoplexy,"†—a contribution to pathology of the highest value.

It would have been necessary to have apologised for making such special reference to the fatty degeneration of the heart which was observed, had not the subject of that common change the widest possible relation to the whole question of muscular irritability, whenever, however manifested.

The relation of such degeneration to the irritability of the heart is every now and then emphatically exemplified by the action of the organ suddenly failing, and as suddenly producing death. The proper stimulus is not withdrawn, but the damaged fibre fails to respond: the stimulus cannot act on it, as galva-

* The just published volume of the Royal Medico-Chirurgical Society contains a most admirable contribution, by Dr. Quain, on Fatty Diseases of the Heart.

† Since published in the *MEDICAL GAZETTE*. Fatty degeneration will, it may be fairly anticipated, be the means of explaining some forms of paralysis, both cerebral and spinal, some diseases of the special senses, and some affections of the mind, especially in aged people, whereof the immediate cause is at present hidden. In a case of nearly complete blindness (the subject of which was a patient of Mr. Hall's) the optic nerves were found after death to have most extensively undergone this form of degeneration. They were first examined by Mr. Holthouse, and afterwards by Mr. Dalrymple, who were both quite satisfied on this point. I had the opportunity of examining them.

nism cannot influence an inirritable muscle. It must be observed that a heart, wherein fat has taken to a serious degree, the place of the proper irritable tissue, may be equal to ordinary, though not to extraordinary, occasions. Shock of mind or body, intense emotions, whether of joy or sorrow, syncope, and all accidents and diseases which kill quickly by asphyxia, must obviously be far more perilous to those whose hearts are thus affected than to others; means of recovery would be lost in them which might succeed in others; the suspended animation might be death in them which would not in others. And every cardiac fibre is impaired in use just in proportion as it is in texture, whilst the entire destruction of the irritability of a single one is a type of what may eventually happen on a large, and perhaps fatal, scale.

In some cases of the change, the voluntary muscles, from having extensively sufficed in like manner, would probably be found less susceptible of galvanism than they commonly are. It is not pretended that this would have been discovered, had a trial been instituted, in the instance I have mentioned, for the degeneration of the heart was not in any sense nearly so marked as it is oftentimes; and the contractions of the muscles, seen after dissolution, lead to the conclusion that their fibres were entirely or almost sound.

Nothing can be plainer than that this degeneration may greatly modify, and, at times, prevent every kind of muscular action. A cause of cramp, it may be assumed, would not affect an excessively fatty muscle as it would another; nor would galvanism, nor strychnia, nor heat, nor cold, nor emotion, nor the will, nor any other sort of known excitant; neither, *anteris paribus*, could we so reasonably look for post-mortem contractions in such a muscle as in one unimpaired. And we may safely believe that, amongst the causes which may prevent, or aid in preventing, the occurrence of post-mortem contractions in some cases of sudden death by apoplexy, the change in question merits distinct notice.

Certainly such contractions could not occur in the altered parts, no matter what the circumstances of death, in such a case as that described by Vieq d'Azyl, the subject of which had almost all the muscles of the leg converted into

fat or cellular tissue, and "was obliged in the latter part of his life to walk with crutches."* We must not, of course, ever confound the fat deposited upon, with that which takes the place of, a structure—for there is a wide difference between addition and destruction—nor suppose a part to be necessarily degenerated because largely and perfectly surrounded by it. "Fat," says Mr. Paget, "accumulated in tissue round a part is a very different—probably an essentially different—thing from fat within it: the one is compatible with perfect strength; the other is always a sign of loss of power. In the muscles of some fish—the eel especially—it is hard to get a clear sight of the fibres, the oily matter round them is so abundant; but the fibres are peculiarly strong, and, in their own texture, make a striking contrast with the fibres of a degenerate muscle in which the fat is in great part within."†

It might have been laid down from ordinary reasoning that the structural state of muscles has much to do with the post-mortem contractions which happen in them, and that it could not be otherwise; nor need we wonder that males should manifest them more frequently than females, and the strongest males most of all. It may be, occasionally, that the reason of some muscles of the same subject contracting to the exclusion of others is, that they are more irritable in consequence of being better nourished.

We need not be too surprised at the after death contractions of cholera being so partial and disuniform: for only let us fancy the very varying states of the muscular fibre existing in different instances at the time of dissolution; the unlike degrees in which this fibre has been exhausted in the course of the disease; the diversified states of its nutrition; and the dissimilar condition of the blood in its vessels; and we shall, to rest here, see no just cause for extraordinary amazement. The physical state of man—to say nothing of his mental—is never, perhaps, exactly the same throughout any two given minutes of our existence singularly impossible.

* See Corvisart's oblique version of the Muscular Tissue as a Fatty Substance." *Dis-1862.*

† See Lectures on Nutri Atrophy, Man. Chap. 11.

for ever fluctuating. Never, as Bichat insisted long ago, shall we understand life's mechanism in the sense that we comprehend the workings of instruments of our own invention; but we shall be perplexed always as to many matters, because we have not *all* the data which their solution requires, and, from the very nature of the problems, cannot, nor even reasonably hope to, have.

These contractions come and go much as cramps do during life; a renewal of irritability appears indispensable to the continuance of both sets of actions, and its temporary exhaustion accounts, apparently, for their so common intermittence. The varying periods at which they begin after dissolution is, it may be imagined, in some way connected with unlike conditions of the fibræ; at the moment of dying, as to the exhaustion or renovation of their power; and in the interval between the last expiration and their commencement it is not improbable that their force may be renewed: for there are facts to show that irritability may be restored or augmented, of course within limits, even after the circulation of the blood has ceased. The cause of these movements in the dead might in some instances, had it acted in the living, have provoked cramps. But one thing seems certain: they generally suffer most from cholera who have the most irritable and least easily exhaustible fibræ at the time of its attack, the muscular energy heretofore so valuable to, and, perchance, by some men envied, them, becoming subservient to their exquisite agony, and rendering them liable, beyond all others, to those contractions which happen, sometimes, after the end of life.

Westminster Hospital, Sept. 25, 1850.

[To be continued.]

EMPLOYMENT OF IODIDE OF POTASSIUM IN CIGARS FOR CONSUMPTIVE PATIENTS.

M. CHARTBOULE has suggested the idea of the administration of iodide of potassium in cigars, as a method by which, in cases of phthisis, the salt will be more rapidly absorbed and more surely effect the cauterization of the tubercles (!) It is further stated by MM. Piory and Cl patients who have made indicated cigars have constant marked improvement in them.

An apparatus has been devised to prevent irritation of the larynx.

ON THE ORIGIN, CAUSE, AND NATURE OF CHRONIC OVARIAN TUMORS.

By EDWARD JOHN TILT, M.D.

Senior Physician to the Paddington Free Dispensary for the Diseases of Women and Children, &c. &c.

[Continued from p. 449.]

Predisposing Causes.

If we conformed to current opinions, our chapter on the determining causes of chronic ovarian growths would indeed be short; for they are generally pronounced obscure and unintelligible: and so, indeed, they are, to those who are ill acquainted with the physiology of the ovaries, and who expect to find in the dim memories of their patients some *one* cause for a tumor, they are only asked to cure when it has attained a considerable size. If, however, we interrogate an intelligent, self-observing patient, notwithstanding the time that may have elapsed since the commencement of the disease, she will generally tell us that previous to the development of the tumor menstruation was accompanied by more or less intense dysmenorrhœa, or that some fall, or other accident, had occurred during menstruation, or at the time of its cessation, which accident suspended its flow, and brought on prolonged pain in the ovarian region. She may then add, that these pains seemed to have nothing to do with the tumor; that they left her, and she was cured; but still on further inquiry she will often own that the pain returned in the same way for several times before she became aware of the existence of a small tumor. The length of time which often elapses between the origin of a tumor and its attaining a considerable size, no doubt renders an increased acuteness necessary in the medical adviser; but the causes of chronic ovarian growths are as easily detected as those of any other complaint. We have already indicated the conditions which predispose to the growth of these tumors, and we have added them to be predisposing causes of inflammation of the ovaries. The same causes are, also, those of acute ovarianitis. We shall first assign those which have been assigned as causes of chronic ovarianitis.

nic ovarian cysts, and then inquire into their modus operandi. My friend, Dr. Chereau, who has done so much for ovarian pathology, has given (*Union Médicale*) a specification of the causes of ovarian dropsy in 179 cases wherein they could be detected. Mr. S. Lee has given 36 cases wherein the specific causes could be assigned; and on adding to these 34 cases which have come under our own observation, we obtain a total of 248 cases, the various causes of which stand in the following proportion:

Marriage	30
Parturition	47
Suppressed menstruation	38
Cessation of menstruation	10
Dysmenorrhœa	28
Abortion	15
Exposure to severe damp and cold	31
Blows and falls on the seat, &c.	15
Disappointed love (Mr. S. Lee)	1
Violent fit of anger	1
Appearance of an eruption (Mr. S. Lee)	1
Other causes (Chereau)	82
Total	248

This table forcibly shows that in the majority of cases the rise of ovarian growths not only often coincides with the morbid excitement of the ovaries, and with the perturbation of their functions, but even with their natural performance. In certain predisposed subjects matrimonial influences excite the development of the morbid as well as of the physiological cell; and the effect of conception in the morbid cell is to stimulate it to increased action, acquiring a fresh impulse: it increases with the advance of pregnancy. This influence of the phenomena of parturition on the development of ovarian tumors, which has been too much overlooked of late, was formerly considered as proved thus:—David Manchart (quoted by Morgagni), speaking of ovarian dropsy, says, "that it may be particularly suspected when the tumor has had its origin in a laborious confinement, in puerperal fever, in the gestation of a false conception, or in abortion." The causes ascribed to ovarian dropsy are those which we have shown to be the causes of ovaritis: we therefore conclude that the causes of ovaritis, under certain predisposing circumstances, also produce ovarian dropsy. We shall not again discuss the mode of action of these causes, as we have already done

so with more than usual care in our chapter on the causes of subacute ovaritis.* An approximation of the comparative degree of frequency of chronic ovarian diseases in married and in single women may be derived from the following table, wherein we have embodied the cases which were collected by Dr. Chereau, Mr. S. Lee, and various others, as well as those observed by Bluff and ourselves, in which cases it has been distinctly stated whether the patients were or were not married:

	Married.	Single.
Chereau (<i>Union Médicale</i>)	160	110
S. Lee (<i>on Tumors of the Uterus</i>)	99	87
Bluff (<i>Experiences</i>)	15	6
The Author	26	14
Total number of cases.	290	197

Thus, contrary to the opinions of Drs. Ashwell and Nauman, and others, we are led to admit that those who have been married, and who have been most subject to the manifold vicissitudes of sexual life in our highly civilized societies, are most liable to this disease. J. Jefferson is of opinion that women married late in life are the most prone to it; and in this Professor Recamier agrees, and adds, particularly so if the marriage be not followed by childbearing. Glancing at other supposed causes of ovarian disease, we find that prostitution has been considered by some as favouring its development: but while we have good evidence to show that this cause produces subacute ovaritis and inflammation of that portion of the peritoneum which enfolds the ovaries, we have no facts to prove its influence in producing ovarian tumors. Much has been ascribed to onanism; but vague assertions only have reached us, not positive facts: it stands to reason, however, that pernicious habits, by reacting on the ovaries, must increase any morbid action which may pervade them; a similar result may be produced by any hæmorrhoidal tendency, and the pressure of impacted feces; and the obliteration of the ovarian vein has also been given as a cause (Douglas, *Philosoph. Trans.* vol. i. p. 122.) Before attempting to show how the

* On Diseases of Menstruation, and on Ovarian Inflammation. By the Author.

causes of ovaritis produce chronic ovarian disease, it is necessary to observe that most morbid anatomists admit the inflammatory origin of adventitious cysts. Without burdening ourselves with numerous citations, we shall quote the opinion of one of our most eminent authorities on such matters: "Although the origin of adventitious serous cysts is in a great many cases involved in much obscurity, there are good reasons for believing that it is similar in kind to that of adventitious serous membranes; that is to say, that these cysts originate under the influence of causes which excite inflammation of the cellular tissue in circumscribed portions of organs" (Carswell's Pathological Anatomy). We only affirm, then, that cysts are formed in the ovary by a process similar to that which produces them in other parts of the body; and we also add that, as under healthy circumstances, the ovary devotes its whole energies to bring the menstrual cysts to perfection, so under the influence of inflammatory causes it devotes the same energies to produce encysted growths of a morbid nature. In no system is inflammation more susceptible of being limited to a very small space than in the sexual system, for the neck of the womb may be severely inflamed without the body in the least participating in it. Huguier affirms that the follicles of the uterine mucous membrane (the ovula of Naboth?) are sometimes found dilated and inflamed, while the other portions of the mucous membrane do not participate in the inflammation. Cruveilhier and other observers have sometimes seen one uterine vessel full of pus, offering distensions about the size and shape of small olives: the fallopian tubes may also be independently inflamed, one or both ovaries may be so; a single ovary may be inflamed in its stroma, in its peritoneal coat, in certain portions of its tissue, or in one menstrual cell which may alone be found containing pus or well organized false membranes. When we talk of partial ovaritis producing the different forms of chronic ovarian disease, we merely affirm that inflammation develops, in a morbid degree, the structural tendencies of our organs. Inflammation of the bony structure will cause a greater deposition of saline particles in their cellular texture, that of the serous membrane an increase of the usual fluids and other products; in

like manner partial ovaritis develops the peculiar cystic structure of the ovaria by exaggerating the prolific tendency of its elementary tissues. When once the cyst is originated, and the balance between secretion and absorption on its internal surface is interrupted to the advantage of the secreting powers, there is no reason why exhalation should not continue predominant in artificial encysted cavities, as well as in those cavities which are natural. We believe inflammation to be as much the key-stone of ovarian disease as it has been proved to be of uterine pathology, and of the structural lesions of other organs. We believe that it lends a hand in the formation of almost every ovarian cyst, even when that inflammation is too circumscribed to be detected by any means we have at our command; and we thus admit that it is alone a cause sufficient for the very numerous cases of fibro-serous variety, and of ovarian growths, even when they are more or less solidified into cartilage, fibrous substance, or bone. If, however, the blood be loaded with constitutional impurities, with the occult seedlings of cancer, or the original elements of that protean diathesis called scrofula, the existence of which is clearly established, however difficult it may be to define it characteristically, then, if the ovaria are under the influence of any of the causes of ovaritis, they will withdraw from the blood which flows continually towards them the elements of disease, and will so assimilate them as to build up cancerous (colloid) encysted ovaria. The warp and woof of the cancerous tissue is afforded by the primitive structure of the organ. The cancerous diathesis finds the rough materials which are to be employed, and inflammation is the all-powerful agent which works up this rough material into the tissue of the organ. Thus we account for the production of areolar cancerous ovarian cysts.

When the follicular multicystic forms are found to exist in patients presenting signs of a scrofulous tendency, we can then in a similar way account for the strange and different productions we have described; but in many cases we cannot explain them by any constitutional affection. We must, however, bear in mind that it is but fair that the organ which has within it sufficient energy to secrete the living man should

also have the power of giving spontaneous growth to productions of an inferior nature; and that in the whole history of the ovary there is an uniform striving for production, which is equally shown by its physiology and its pathology; and thus, if the organs of increase are useless for fruitful progeny, they will often team with spurious growths. The streams of living productivity having been once made to rise in those hidden walls of our existence, they cannot be dried up. They will often go on producing imperfect growths or forms which, being perfect, can reproduce themselves; and so it is throughout the whole creation.

The inflammatory origin of ovarian cysts is not a new hypothesis; at least, as early as 1782 the German writer inculcated that doctrine in the following words:—"Interioris generationis partes, præsertim ovaria fere nunquam liberantur ab assidua et sæpius repetita irritatione et humorum congestione; quæ vitiosæ tantum irritata ovula alterantur, et quandoque humoribus inundata tumescunt ut hydropici status initia præbeant" (Kruger, Dissert. Gœttingue, 1782).

A more modern writer in the same country (Meissner) also says, "Chronic ovaritis is the mother of all ovarian degenerations." Cruveilhier, Ricord, Caseau, Chereau, and numerous other writers, have entertained an opinion in same degree similar; but we have attempted to make it our own by the development we have given it; and we think these views are not only true in pathology, but eminently useful in practice; and that those ovarian cystic growths, which are the opprobrium of our art, would be much less frequently met with if the subacute ovaritis from which they spring, and by which they are fostered, was more carefully sought for and more energetically treated. Nature is, after all, the best court of appeal in pathological as well as in all other questions: so, without referring to olden times, we shall mention a few contemporary cases, wherein ovarian cysts have had an inflammatory origin.

A woman, 21 years of age, was, during the menstrual period, exposed to the influence of damp and cold. The catamenial flow was stopped, inflammatory symptoms appeared, and a small tumor was soon detected, which in three

years reached the abdomen, and was extracted successfully by our friend Dr. F. Bird, who says he has seen several similar cases (*Lancet*, June 15, 1845).

Catherine Staub, 25 years of age, and in perfect health, received a kick in the abdomen during the menstrual epoch. The flow ceased, and soon after an ovarian tumor was discovered, which in a few years caused the death of the patient (*Arch. Gén. de Méd.* tom. iv. p. 582).

Mrs. Palmer, 39 years of age, who always suffered from dysmenorrhœa, felt acute pain in the right ovarian region; pain increased by pressure, and soon after tumefaction was detected, and gradually increased (*Lancet*, May 18, 1839).

An unmarried woman, 30 years of age, under the combined influence of cold and violent fit of anger during the menstrual period, was seized with acute pain in the hypogastric region, accompanied by shivering, fever, and hysterical symptoms. The menstrual discharge stopped, and a considerable ovarian tumor was speedily developed. The patient was tapped by the vagina, and eventually cured (Pr. Hirtz, Thèse de Strasbourg, No. 67, 1841).

In the *Lancet* of September 9, 1846, we have recorded a similar case, wherein a large ovarian growth evidently arose from acute ovaritis.

Madame Dubois, 24 years of age, first menstruated at 16, and was always subject to considerable disturbance of the function. She married, and was confined the following 21st February, 1822. Twenty days afterwards she travelled nine leagues on horseback. The weather was bitterly cold, and she felt acute pains in the ovarian regions. Flooding came on; but by appropriate remedies this subsided, and nothing remained but a dull and deep-seated pain in the right ovarian region. For this, however, she did not consult us until three years after, when we found a large ovoid tumor, about a foot in diameter, springing from the right side, and occupying nearly the whole abdomen.

On March 20th, 1827, the sufferings of the patient from abdominal distension were so acute that, although fluctuation was not manifest, tapping was resorted to. A first puncture only brought out 8 ounces of serum; 1 on

tapping more to the right, 35 lbs. of an unctuous liquid were withdrawn. The patient recovered sufficiently to resume her daily avocations; but the tumor re-filled, and, after several tapplings, her constitution gave way, and she died. On a post-mortem examination a multilocular cyst, weighing fifty pounds, was found in the abdomen (T. Butand, *Thèse de Montpellier*, Nov. 27, 1832).

We shall conclude with another case, wherein the origin and form of the disease was inflammatory, and where a successful termination, was brought about by the judicious treatment of Mr. Phillips. Mary Addison, was admitted into the Westminster Hospital, under Mr. B. Phillips, in January 1849. She is of a thin, spare habit, and 86 years of age. She menstruated for the first time at 16; and since then, up to the time when she became affected with ovarian dropsy, menstruation was regular and painless. In June 1846, during her menstrual epoch, she was seized with a sharp pain in the right iliac region, which lasted eight days: there was also swelling in the same spot. The catamenial discharge appeared, and went on as usual. In August 1847, she was seized with a similar sharp pain in the right side, accompanied by swelling. The symptoms were more severe than on a previous occasion, and lasted three weeks. She was bled in the arm, and had fomentations to the side. As in the previous attack, the menstrual flow followed its usual course. The patient does not remember whether it preceded or followed the appearance of acute pain in the right iliac region. In February 1848, while grinding coffee, she felt a return of acute pain in the side. This increased, and was accompanied by swelling in the iliac region, which was distinctly felt by her master, Mr. Bayntin, of Lower Eaton Street, who ordered leeches, gave purgatives, and employed other judicious treatment. In the meantime the menstrual flow appeared, went on as usual, and naturally made Mr. Bayntin give a favourable prognosis; but as the patient did not mend, he sent her to St. George's Hospital. Notwithstanding the energetic treatment prescribed by Dr. Barnes Jones, and the numerous applications of leeches (78 at different intervals), to the right side, the tumor, in less than a month, increased

to the size of a child's head. There seemed to be partial peritonitis in the epigastric region, as for several days there was manifest eripitation to be felt on pressing to and fro the teguments in that region. The pain was also so intense, and the general symptoms so considerable, that some of those who watched the case thought suppuration was going on in the tumor. It was not so, however; for Dr. B. Jones, having thought it advisable to have the tumor punctured, Mr. Tatum made an exploratory incision, and withdrew a tea-spoonful of glutinous liquid tinged with blood. The patient was relieved by the puncture. The tumor, however, increased; but, as it was no longer accompanied by acute local symptoms or fever, she left the hospital. Some time after this she entered St. Bartholomew's Hospital, where her abdomen was covered with a large plaster. When cured of the violent erysipelas occasioned by this plaster, she left that establishment. In the hope of finally obtaining relief, she some months afterwards entered the Westminster Hospital; and here began Mr. Phillips' treatment. He plunged a small trochar into the cyst; and, withdrawing a little sero-purulent matter, he intended leaving the tube in the cyst, to promote the inflammation of its internal cavity, but the tube fell out after remaining there seven hours. Its introduction produced considerable inflammation of the tumor, and when this had subsided Mr. Phillips again punctured the cyst, and introduced a small India-rubber catheter, which was left in for several days, during which time a considerable quantity of sero-purulent fluid trickled out. This was followed by considerable inflammation of the cyst, which greatly increased, and there was evidently a pointing of the tumor in the spot where the cyst was punctured. We thought the tumor was going to burst, and we anticipated the possibility of the patient being radically cured by adhesion of the walls of the sac. We were, however, deceived. The inflammatory symptoms abated, the cyst diminished in size, and Mary Addison, instead of appearing as though seven or eight months advanced in pregnancy, presented no preternatural enlargement of the abdomen, although a hard globular tumor was easily detected by manual examination. She

was for several weeks confined to her bed, by an acute attack of rheumatic gout; otherwise she would be moving about, pursuing her usual avocations.

The patient called on us on the 6th of September last; she had recovered her health and strength. By a careful abdominal examination, a small lump about the size of an egg could be detected on the right side, but it was not painful on pressure. Menstruation, which had ceased during the patient's sojourn at St. George's and St. Bartholomew's, had returned once previous to the tapping of the cyst by Mr. Phillips; it then ceased, to reappear in July last, and has continued regular and painless as before the development of the tumor. There is, however, during menstruation, a greater amount of swelling; and when she gets up suddenly, or walks fast, she feels "a little sharp pain," which lasts about a minute or two.

Remarks.—We have given this case entire, as, in more than one point of view, it is worthy of our attention. The cure by reabsorption of the purulent contents of the cyst is in itself interesting, as in this disease we have as few means of effecting a radical cure. The acute nature of the tumor, its attaining the size of a child's head, and being attended by the symptoms of suppuration in the short space of a month, is also well worthy of remark. The origin of the tumor in sub-acute ovaritis is the reason of our recording the observation in this place. Three successive attacks probably took place, each attack being more severe than the preceding; each was accompanied by the menstrual flow, which in the first attack effectually relieved the patient's sufferings, did so imperfectly in the next, but in the third it had no effect. The fact of the disappearance of the tumor by the absorption of its contents, and the subsequent appearance of acute rheumatism, is also interesting. Mr. Phillips has seen similar cases, and looks on the facts as related to each other as cause is to effect; but Mary Addison was subject to rheumatism, having already had an acute attack at St. George's Hospital, and previous attacks in her youth.

8, York Street, Portman Square.
October 1850.

REMARKS ON THE VITAL STATISTICS OF THE BOROUGH OF PLYMOUTH.

FOR THE YEAR ENDED ON THE 31ST OF
MARCH 1850.

By Dr. W. H. HAMMOND.

Barbarians in Calcutta, cholera spread with destructive rapidity to every town and village within an area of many thousand square miles, from Silhet in the east to Cuttack in the west, from the Delta of the Ganges to its confluence with the Jumna at Allahabad. Proceeding from this extensive district in three directions, it totalled a south-west direction along the Circar coast to Madras, which it reached in twelve months; and it also arrived at Ceylon, whence, towards the close of 1817, it was carried to the Mauritius in the Topaz frigate.

Proceeding along the eastern shores of the Bay of Bengal, it took twelve months to reach Arracan, whence it traversed the Malay peninsula to the Iang, where it swept away three-fourths of the population. It next spread over the islands of the Eastern Archipelago; and, on the west coast of Borneo, it carried off the whole of a Dutch garrison but one who witnessed its fury. Arriving at Canton in 1820, it attended in the following year to Peking, and passed the six succeeding years in decimating the dense population of that extensive empire. At length, in 1824, it crossed the celebrated wall, and, carrying destruction among the semi-barbarous population of Tartary, it invaded a large portion of Mongolia.

Again, branching from Calcutta as a centre, taking its route along the valley of the Ganges to Bundelkund, it swept off no fewer than 8000 of the army and camp followers there under the orders of the Marquis of Hastings. Pursuing the course of the Jumna, it arrived at Delhi, Ratah, and Surampore, in August 1818, and spread from thence to Nepal, on the southern slope of the Himalayan range, and to Bombay on the western coast; hence, following the sea line, it travelled on to Cape Comorin, the southern extremity of Hindostan.

After a sojourn of twelve months

these districts it penetrated further into Asia, and made an abrupt lodgment in Ooleypore, the capital of Chittore, and, during the space of two years committed its usual ravages in this town and its adjoining territories. Here it lingered for two years, at the end of which it broke into Persia, where it took up its head quarters in the three principal sea-ports,—Muscat, Bushire, and Bus-sarah,—carrying off at the former 10,000 victims; and at the latter, situated at the mouth of the Tigris, 18,000, or nearly one-third of the population, in the brief space of 11 days, or at the daily rate of above 1,633. Ascending the Tigris, and its tributary the Euphrates, of Scriptural celebrity, it arrived at Bagdad; the city of the Caliphs, which was at the time besieged by the Persians: here it swept away, with indiscriminating fury, alike the besiegers and the besieged.

Continuing its course along the banks of the Tigris it reached Aleppo, the capital of Syria, one of the cleanest and best built towns in the Turkish dominions; and, pursuing simultaneously the course of the Euphrates, it effected a lodgment in Erzeroum, the capital of Armenia or Turcomania, a considerable town, distant five days' journey from the Black Sea, and ten days' from the frontiers of Persia, reaching both these places in the summer of 1822. From Erzeroum, the Turkish army, in its retreat, carried it to Bakou, near the 40th parallel of latitude, on the western shore of the Caspian. Hence it spread to Astracan, at the mouth of the Volga, where, after immolating 144 victims, it appeared for a time to subside; while from Aleppo it extended to Antioch, and other parts of the Levant.

Halting then for about six years on the eastern frontier of Europe, it reappeared with renewed virulence, in the summer of 1829, at Orenburg, a town N.E. of Astracan, 400 miles from the mouth of the Oural, on which it stands. In the July of 1830 it revisited Persia, extending its ravages from Astracan, at the mouth of the Volga, to Saliany, at the mouth of the Cur, along the whole western shore of the Caspian.

Ascending the Cur it reached Tiflis, and thence advanced along the Terek and the Kuma into Caucasus; while, following the Volga from Astracan, it advanced to Sarataff, and from thence reached Moscow on the 14th of Septem-

ber, 1830. Thus established within the limits of Europe, it set the vigilance of quarantine at defiance. It spread rapidly to Petersburg and the shores of the Baltic. Descending the Don to Azof, and the Black Sea, it arrived at Odessa; whence, ascending the Danube, it reached Vienna in August, 1831, during which year it infected Austria, Germany, Hungary, Egypt, and Turkey. On the 26th of August, 1831, it was conveyed from Hamburg to Sunderland, and broke out, in the January following, at Edinburgh. On the 14th of February it appeared in London; and, on the 22d of March, showed itself in Dublin, whence it spread rapidly over the whole country. On the 11th of June it made its first onslaught at Coxside, on the eastern side of Plymouth, a low situation bordering on Sutton Pool, whence, as from a focus, it spread rapidly, 77 cases and 31 deaths taking place during the 19 days which remained of the month,—averaging 4 cases daily, and about 8 deaths in 5 days. Among the deaths were those of a woman named Eoderich and her daughter, aged, the former, 42, and the latter 19, years, who expired at No. 11, Higher Street, within half an hour of each other. In both these cases the transfusion of albumen and salt into the veins was without effect.

About the 2d of July it broke out in Devonport. It reached Exeter on the 19th of July, and attacked, in the 12 first days of its existence, 45 persons, of whom 19, or above 42 per cent., died, the daily average of attacks being 3.2. Its duration here was 100 days, in which it proved fatal to 345 out of 1,145 who were attacked, or above 30.39 per cent, the mean daily mortality having been 8.45 per cent.: in Plymouth it reached to nearly 6 per diem.

In the 17 years which elapsed from its outbreak among ourselves in 1832 to its return in 1849, we can hardly believe that it had wholly ceased to exist, although no accounts of its effects have reached us: its hidden fires may have slumbered without ceasing to exist.

Dating from its appearance in 1817 at Jessore, to its establishment at Plymouth in June, 1832, we find a total interval of 17 years occupied in carrying destruction over at least one half of the known portions of the globe. But this is far from being the true limit of its actual duration; for we find it continu-

ing its ravages for a farther term of 5 years: in Spain and Portugal in 1833 and 1834; in Italy in 1836 and 1838, and at length at Malta, where it is supposed to have expired, in 1837. During its existence in this country, from its

first appearance at Sunderland, it attacked, as the official reports inform us, 187,060 persons, of whom 84,533, or about 45 per cent., recovered, and 52,547 swelled the black catalogue of mortality. These were distributed as follows:

	Cases.		Recoveries.		Deaths.	
	Number.	Centesimal Proportion.	Number.	Centesimal Proportion.	Number.	Centesimal Proportion.
England and Wales.	62,326	45.47	41,600	49.21	20,726	39.46
Ireland	54,552	39.80	38,381	39.49	21,171	40.29
Scotland	26,202	14.73	9,552	11.30	10,650	20.25
Aggregate . .	187,060	100	84,533	100	52,547	100

In London, out of 11,020 cases, 5,745, or 52 per cent., recovered, and 5,275, or 48 per cent., died.

Let us now endeavour to trace its progress in its last approach to our shores.

Its first authentic reappearance was at the beginning of the hot season in 1845 at Cabool, only four years before it reached us. By the 10th of July it had reached Umballa, one of the filthiest towns in Lahore, and the best fitted for its reception and propagation. We cannot, therefore, be surprised to learn that in the brief space of 57 days, or up to the 5th of September, it attacked, exclusive of natives not included in the returns, 322 men of the 31st Regiment, or above 5 per diem, of whom 142, or 44 per cent., died. By the 12th of the following June it had reached Teheran, where it swept off 300 victims daily. In February, 1847, it was at Kouba. Previous to this, on the 16th of November, 1846, a few cases had occurred at Saliany and Leucaran, places which it had visited 16 years before, and in which it is probable it had never been wholly subdued, although the mortality it occasioned may not have been of sufficient magnitude to attract particular notice.

In March 1847, after a fallacious interval of repose, from which it appears to have acquired a greater concentration of virulence, we find it raging with augmented fatality in the regions lying beyond the Caucasus; whence it diverged in the following month in three different directions: extending first to the north along the shores of the Caspian, as in 1822; next to the north west, in the direction of the mountains and the Black Sea; and thirdly, to the

west, arriving at Tiflis, the capital of Georgia proper, on the 17th of May.

Of these three divisions, the first, coasting the Caspian, reached Astracan in July, and, out of a population of 31,000, it attacked 5,195, about 16 per cent., or nearly one-sixth, of whom it carried off 3,131, about 60 per cent., or nearly two-thirds. Next, penetrating the regions watered by the Don, and occupied chiefly by the Cossacks, it attacked 12,651 of them, and proved fatal to 7,617, or above 55 per cent. At Woronesch, which it reached on the 4th of September, it raged with such fury as to attack 420 daily, 150 of whom, or nearly one-third, sank under the assault. The date of its arrival at Moscow is not known with precision, but few parts of the empire, Asiatic or European, were free from its ravages during the summer and autumn of 1847, in which time it attacked, as we are officially informed, no fewer than 300,000 individuals, to one-third of whom it proved fatal.

On the 24th of October it reached Constantinople, where it found an appropriate soil for its reception and propagation in the peculiar habits of the Turks.

September 1848 witnessed its simultaneous arrival at Vienna, Paris, and Hamburg, from which latter place it crossed over to Britain about the beginning of October.

In 1831, cholera made its first appearance at Hamburg early in October, and reached Sunderland, where, if I recollect rightly, it broke out in a ship from Hamburg, on the 26th of that month.

In 1848 it reached *Hamburgh* as early as the 1st of September, but does not appear to have gained a footing among ourselves before the end of that month, or beginning of October, when it showed itself simultaneously among the shipping both at London and Hull, — parts with which *Hamburgh* maintains a considerable commercial intercourse.

Sporadic cases of cholera, indeed, possessing all the unmistakable characteristics of the Asiatic or malignant form, had previously appeared, *rari nantes in gurgite vasto*, in both these places, as early as the preceding June, but these were not of that epidemic character which marked the disease afterwards, and can only be compared with the three or four similar cases which appeared among ourselves in the month of June immediately preceding the fearful outbreak in July 1849.

During the cold months of winter the malady slumbered, and appeared to be extinct; but, as the warm weather advanced, it awoke with renovated energy, and spread rapidly over almost every part of the country, carrying dismay and terror in every direction, and baffling the utmost efforts of science and vigilance to stay its progress or mitigate its destructiveness.

Unwarned, however, by the steady and unmistakable course of its advance—unwarned by the lessons of the past—heedless of the confident predictions of those whose memory faithfully retained the recollections of 1832—cholera in 1849 found us, with a very few honourable exceptions—such as that of Exeter—not only wholly unprepared to resist its invasion, but almost courting its approach by our utter disregard of sanitary improvements,—the window-tax still excluding the light and air of heaven—and the supply of pure water, and the drainage of our streets, utterly inadequate to the growing wants of the community, and the wholesome aphorism of *venienti occurrere morbo* apparently obliterated from our thoughts; while, with the listless apathy of Turks, we awaited the arrival of the destroyer, nor looked to our ramparts till the enemy had possession of the citadel.

We flatter ourselves, even now, that the danger has passed, and we may safely rest on our arms: we relax in our vigilance, and relapse without thought into our accustomed habits of criminal

negligence; while occasional sparks are bursting from the smouldering embers around, to remind us that the fire is suppressed, but not extinguished, and may at any moment burst out anew with fresh and resistless fury.

Notwithstanding the imperfect character of the meteorological observations made of the two periods of cholera, they expose some of the popular fallacies with respect to the origin of this most mysterious scourge; by some of which it has been attributed to some supposed deficiency of atmospheric electricity—to excessive heat, or moisture, or the variations of atmospheric pressure.

It will, however, be seen, on a careful comparison of the meteorological tables that there was the same alternation of weather and atmospheric pressure which occurs in ordinary seasons, and that there was little, if any, want of the usual amount of positive electricity. Hence the latent cause must be sought in some other direction than that to which we have hitherto been accustomed to look.

The following table of the mean monthly pressure and temperature, as recorded during the last nine years at Greenwich, may be serviceable as a farther standard of comparison, the months selected being those in which cholera was present. In the last year of the series the pressure and temperature for October and November are wanting.

The writer of an excellent article on Cholera, in the Companion to the Almanack for the present year, to which I have been indebted for the history of the progress of cholera, draws the following parallel between the two attacks of 1832 and 1849:—

“The main points in which the recent visitation of cholera appears to differ from that of 1831-2 are the longer continuance of the disease in the places visited, the greater tendency to subside and reappear, and the higher mortality” (p. 107).

To which he might have added, the greater rapidity of its advance into Europe.

The first of these points of difference has been strikingly exemplified in our own town, where its duration exceeded by four weeks that of 1832; but as to the increased mortality, when due allowance has been made for the advance

of population, it will be found that among ourselves it was lighter. In 1832, out of a population of 31,527, we lost by cholera 779, or 1 out of about 41; in 1849, out of a population of 39,571, or 8,044 more, it carried off 819, or 1 out of 48.

In 1832 the greatest intensity was in August, when 500 deaths occurred; while in 1849 the period of greatest intensity was divided between August and September, when 602 deaths took place, of which 290 belong to the former and 312 to the latter month. Of the 290 deaths in August, 139 took place in nine days, between the 10th and 19th—namely, 127 in St. Andrew's district, and 12 in that of Charles; while of 160 deaths in the same space of time in September, between the 15th and 24th, 39 only occurred in the former, and 121 in the latter; illustrating, in a striking manner, the observation made by the writer in the Companion, as to the subsidence and revival of the disease; for, at the time of the fresh and unlooked-for outbreak between the 14th and 15th of September, in Higher, Gaskin, and Moon Streets, in the district of Charles, the mortality in the larger population of St. Andrews was rapidly on the decline.

On a centesimal comparison between the population and mortality of the two periods, we still find the favourable balance on the side of 1849; the mortality of 1832 amounting to 2.46 per cent, while in 1849 it was only 2.06 per cent, being a difference of nearly one-half per cent.

But the two attacks seem to have

differed in other respects: in 1849 they were neither so sudden nor so violent; instances did not occur of individuals dropping down in the street, and expiring on the spot: nor do the fears of the inhabitants appear to have been so much awakened. This may perhaps have arisen from greater familiarity with the complaint, and from having been prepared to expect it, as well as from its almost exclusive restriction to the poorer classes.

We have now examined the more prominent points of distinction which present themselves, and shall conclude with directing attention to the singular predilection it manifested for water, following for the most part the direction of rivers, and the sinuosities of coasts, and rarely crossing any extensive tracts of unwatered land.

THE PUBLICATION OF SCIENTIFIC DISCOVERIES AND IMPROVEMENTS.

If you do make discoveries—if nature and education have made you great enough for that—be not mean enough to run away into the dark with it; skulk not out of good company to fatten on your good fortune, for recollect that you have borrowed as much from the liberality of others as your own genius will ever repay to the great world of science. If there be anything revealed to you, give it to the light, that others may interpret, and test, and prove it. Recollect that the apostles of science have all things in common; and if you meanly secrete a part of the wealth which belongs of right to the general stock, you deserve to be carried out of the profession, like Ananias, feet foremost.—*American Journal of the Medical Sciences.*

MEDICAL GAZETTE.

FREDAY, OCTOBER 10, 1850.

THE American Medical Association has rendered good service to the profession by the publication of its recent Report on the Comparative State of Medical Education in Europe and America. It is more than four years since a Committee was first appointed at New York to inquire and report on the adoption of a uniform and elevated standard of medical education throughout the United States. A preliminary report on this subject made its appearance in 1847; and this has been followed by the more elaborate document published in the last volume of the Transactions of the American Association. The first Report points out the defects of the American system; the second compares this with medical education in the various countries of Europe, and contains resolutions on the best method of raising the character and acquirements of medical practitioners in the States.

There can be no doubt that the most durable reform of medicine will be that which improves medical education; and perhaps this has been hitherto too much lost sight of in the attempts at legislation in this country. The desire has been rather to define and limit the powers of Universities and Colleges already established by Act or Charter, than to go to the fountain head, and remove those anomalies which are known to exist in medical education. There are three kinds of curricula in England, and a still greater number in Scotland and Ireland. Such differences ought not to exist; there should be some uniformity in the system of instruction, in its duration, and in the examination to which the candidate for medical prac-

tice is compelled to submit. Our object, however, at present is to ascertain how far the British system is superior or inferior to that adopted in other countries.

The first American Report (1847) tells us very plainly that the European system, defective as it is considered to be in each country, has many advantages over that adopted in England and the United States. In the first place, in addition to the branches taught in American schools, medical education in Continental institutions comprises the several subjects of Zoology, Botany, Comparative Anatomy, the History of Medicine, Hygiene, Medical Physics, and Clinical Medicine and Surgery.

"All these branches, it is true, are not crowded upon the mind during a single session, but are distributed throughout successive years; while clinical instruction, in both medicine and surgery, is reserved for the last year or two, after it is presumed the student has made such advances in his primary studies as will enable him perfectly to understand the lessons which are taught him at the bedside of the patient."

In reference to the time allotted for education, and the mode in which the examination of the candidate is conducted, we find the following remarks:—

"Instruction so full and so complete must of necessity require a lengthened period for its accomplishment: hence we find that in France and Austria the term of lectures is extended to a fraction more than four years; in Germany to three years and four months; in Great Britain to two years; while in the schools of our own country two sessions of four months each are alone sufficient to entitle the candidate to an examination. And if we extend our inquiries a step further, we shall find as great a contrast in regard to the examinations by which the qualifications of candidates are tested. Nowhere, we believe, except in England and America, is the qualification made to rest upon a single viva-voce examination; but throughout the period of the student's probation, repeated examinations are held at stated

intervals. By proceeding in this manner not only is the qualification more accurately ascertained, but certain branches are completely mastered before others have been commenced. Thus we learn from Mr. Surgeon Wilde's work on Austria and her Institutions, that at Vienna the student is compelled to undergo an examination at the end of every six months by each professor whose lectures he may have attended. During the fifth year, which completes his term of study, he is subjected to two other examinations, besides giving a detailed history of two or more clinical cases, and defending in public a thesis written in the Latin language. In Prussia four examinations are required. When the pupil has satisfactorily completed the third, the honours of the Doctorate are conferred upon him; but he is not yet permitted to enter upon the practice of his profession. To enjoy this privilege a more rigid ordeal must be passed: he is now called upon to demonstrate his *practical* acquaintance with the several subjects in which he has been instructed; to take charge of patients under the immediate inspection of his teachers; and, finally, to be questioned by eight of the most distinguished professors of the country in every department of medical science. By a recent decree of the University of France, it is now ordered that examinations shall be held at the termination of each year upon the branches which have been taught during the year: at the conclusion of the whole term of study a final examination is instituted, embracing the subjects taught throughout the whole course. A knowledge of clinical medicine and surgery is also required, and a thesis must be publicly defended."

The period required for education in England is here considerably understated. The English College of Physicians requires five years, the College of Surgeons four years, and the Apothecaries' Society three years of professional study before the candidate can be admitted to examination; and either of these periods contrasts favourably with the two sessions of four months (*i. e.*, a *studentship of eight months*) which qualifies the American graduate to present himself to his examiners.

To a certain extent the objection to the British system is well founded. The University of London has, however, broken through the ancient rule regarding a single *visd voce* examination. With very rare exceptions its examinations are as searching and as *practical* as need be desired.

In the United States there are no fewer than *thirty-eight* distinct institutions engaged in *teaching* medicine, and in *licensing* (!) candidates to practice. These institutions are quite independent of each other, and they appear to be practically independent of the legislature. Thus, observe the reporters,—

"The colleges themselves, resting secure in their chartered rights, may contend against any interference with their several systems of education; although we would fain indulge the hope that some among them stand prepared to listen to that voice which rarely speaks in vain—the voice of public opinion. This it is which now agitates the professional mind from one end of this Union to the other; and this it is which, if not now heeded, will not cease to reiterate its cry. Let but a very few even of our conspicuous institutions demand of their pupils a more extended course of study, and so far from their interests perishing in the attempt, we cannot doubt that an accession to their numbers will ere long reward their efforts. The possession of the diploma now no longer tests the qualification of the man; and it cannot be doubted that the large number of medical colleges throughout the country, and the facility with which the degree is obtained, have exerted a most pernicious influence. Numbers of young men have entered the profession who were not prepared for its onerous and responsible duties, who, after a longer or shorter period of disappointment, have served to swell the list of empirics, or to seek employment by means unbecoming the character of the physician or the gentleman. Nor can it well be otherwise, when each returning spring lets loose upon the community some twelve or thirteen hundred graduates, whose professional existence must depend upon the encouragement they receive."

The suggestion for the correction of these evils is that some of the more prominent institutions should of themselves at once proceed to raise the standard of preliminary and medical education. We quite agree with the reporters that great responsibility rests upon Professors.

"They stand as the guardians, more than any others, of the public weal; for every student who receives the diploma is furnished by them with *prima facie* evidence that he is prepared for that important occupation in which he seeks to engage. And if we admit the supposition that, in any case, he is not thus prepared, it will require the prediction of no seer to forecast the lamentable result. We believe the opinion defensible, that in no profession is it more difficult to estimate just conclusions, as to real merit, than in that of medicine. And hence there devolves upon those who are the most competent to judge, and who have the best opportunity for judging, a vast responsibility to see well to it that none but the truly meritorious should be admitted to the profession under their sanction. From the fact that society cannot in this respect adequately protect itself, the teachers in our medical schools should exercise a guardianship, the more watchful, a jealousy the more keen, and a firmness the more unyielding. With a determination thus expressed, to furnish the community with individuals who have gained the honors of the doctorate solely on account of their merit, it can not be saying too much when we assert that a reciprocal duty rests upon it—a duty which should ever lead to the protection and encouragement of those who have devoted their time and talents to its dearest interests."

"Unfortunately the principle of pecuniary competition in teaching and licensing has too great a sway in America and England to allow this appeal to have that just and universal influence which it should carry with it. There as here, the question too often is, not where the largest amount of instruction in a special branch of medicine can be obtained, but where a *certificate* of attendance, granted, as a matter of course, on the payment of the fee, can be procured at

the smallest cost. The following summary presents a curious picture of the mode in which doctors of medicine (not physicians) are manufactured in the United States. Out of thirty-eight colleges, the Committee obtained answers to their questions on medical education from nineteen.

"In summing up the information obtained from the nineteen colleges, in the order in which the questions were proposed, it was found that the number of students belonging to these institutions during the session of 1845-6 amounted to 2544, including 81 non-paying pupils; and that the number of graduates was 730; the number of professors varies from three to eight. It may be proper to remark that the lowest number here named is attached to the University of Virginia, where the usual branches of medical education are taught, and where the term of study extends throughout the period of nine months. If we exclude this institution from our table, the minimum is five and the maximum is eight. The time employed in lecturing also varies, eleven weeks being the shortest, and eighteen the longest period. Sixteen weeks, however, are devoted to the lectures in a large majority of the schools. The requirements for the degree of M.D. appear to be very general: the candidate must be twenty-one years of age, of a moral character good, his qualifications satisfactory, his thesis passable, and he must have attended two full courses of lectures, to be included within the period of three years' study. In some of the schools a practice of four years, and attendance on one course of lectures, is sufficient to entitle the individual to an examination. Branches are taught in some institutions which are omitted in others, and the manner in which these are distributed is by no means uniform. It appears without exception that the inquiry is made, previous to examination, whether or not all the requirements have been fulfilled, and in some cases unquestionable proof of the fact must be adduced. Evidence of having attended a course of clinical instruction is required in twelve of the colleges, while in seven it is not; and as to dissections, five render it obligatory, and the remaining fourteen are content to urge its recommendation."

From this it follows that the great object in most of the American Colleges is to create M.D.s, and not physicians! If the title be legally conferred, a knowledge of medicine is of no importance as a qualification for practice.

With this for the present we close our extracts and remarks. We shall take an early opportunity of returning to the subject.

Books.

The Cyclopædia of Anatomy and Physiology. Edited by ROBERT B. TOWN, M.D., F.R.S., &c. Parts XXXVIII, XXXIX, and XL. Longman and Co. 1850.

We are glad to perceive, from the rapid succession of the various parts, that this excellent work is approaching completion. We have now before us three parts, comprising numerous important articles under the letter T from *Testis* to *Urethra*. In Part XXXVIII, the elaborate paper on the *Testis*, by Professor Owen, is brought to completion: this portion of the paper is chiefly devoted to the comparative anatomy of these organs. It may be profitably consulted by all students of this branch of science. Two short papers follow; the one on *Temperament*, by the editor, and the other on the *Temporo-maxillary articulation*, by Mr. S. R. Pittard. The two next articles—on *Teratology*, by Professor Vrolik, and on the *Testicle*, by Mr. Curling—are the most important in the Part now before us.

Professor Vrolik has given a complete anatomical description of all the varieties of malformation and monstrosity hitherto observed. The paper is more of an anatomical than of a physiological character, and is profusely illustrated with wood engravings, which render the author's descriptions perfectly clear and intelligible. We observe that Professor Vrolik, who is a high authority in such matters, wholly disbelieves that deformations of the originally well-formed germ can take place as the result of a mental impression produced on the mother during pregnancy. He freely admits that the origin of monstrous births still remains very mysterious. The opinions

on the subject may be reduced to two—i.e., that monstrosity is due—1, to original malformation of the germ; 2, to the subsequent deformation of the embryo, by causes operating on its development. It is in reference to the latter point that the author asserts his disbelief that the mental condition of a pregnant female can have any influence on the embryo, except indirectly. We subjoin an extract containing the arguments of the writer against the view, which has been suggested, by some eminent physiologists:

"a. That malformations seldom, or perhaps never, agree with apprehensions or fears *a priori* of pregnant women (G. Vrolik, T. Zimmer, J. J. Plenck, and Burdach). On the contrary, it often happens that a woman who has once procured a malformation, and is continually troubled by the fear of another similar and occurrence, may become the happy mother of a second well-formed child.

"b. That the *fœtus*, even when a germ, is quite independent; transferred from the ovary into the uterus, it needs for its development a material intercourse with the maternal body, but no *organic* connection; for which reason it can be formed as well without as within the uterus, as in extra-uterine pregnancy; that it stands in no connection, either vascular or nervous, with the body of the mother, and that therefore it is improbable that her mental condition can have any influence whatever upon the form of the *fœtus*.

"c. That malformations occur likewise among the inferior animals—insects, testaceous animals, echinoderms—in which the development of physical life is very imperfect, and the oviparous generation of which must preserve the young from the influence of disordered maternal imagination.

"d. That in the case of twins, as the acephali specially show, one child may be malformed and the other in perfect condition, notwithstanding they were both exposed to the same influence.

"e. That more deeply situated organs, the very existence of which may be unknown to the pregnant woman, may be malformed; as, for instance, the heart, the intestinal tube, &c.

"If now, on all these grounds, I exclude the mental impressions of pregnant women from the ætiology of malformations, I do not mean to deny the influence which, by her somatic condition, the mother may exercise upon the *fœtus*. Thus, if in consequence of mental agitation her body were to suffer a violent shock, this might have a

prejudicial influence on the maternal transmission which takes place between her and the fetus, and the latter might thereby become morbidly affected. There are instances of its being the subject of intermittent fever (P. Russell); of sudden death, occasioned by frightful agitation of the mother (Wienholdt); of jaundice communicated by the mother (Kerckring); of small-pox (Jenner, Montgomery, Friedlander); of syphilis and scarlet fever (R. Lee); all derived from the mother. But all this is entirely different from the effect of mental impressions. It is a material result easily conceived, and of which physiologists need no further explanation" (p. 945).

We may remark of this article, that it displays deep research on monstrosities, and a thorough acquaintance with the subject on the part of the author. We think that its interest would have been heightened had Professor Vrolik, besides types and species, given us a short description of some of the remarkable monsters of modern times, such as the *Siamese Twins*, *Christina Ritta*, and the *Chinese Heteradelph A-ke*. The physiological condition of a monster which survives for months or years is quite as instructive as the determination of its abnormal peculiarities when dead. The physiologist desires to know how the disjointed machinery acted, if it acted at all; but on this point Professor Vrolik refers the reader to the general records of medicine. So far as the classification and anatomical description of monsters are concerned, there is probably no essay or treatise in the English language which can be more profitably consulted than this.

Mr. Curling's paper on the *Testicle* is divided into two sections; the one comprising the *normal*, and the other the *abnormal anatomy*. In the first section, which fills nearly forty pages of the number, the author gives a clear and minute description of the anatomical structure of the testicle and its appendages. As a specimen of Mr. Curling's mode of treating the subject, we quote his remarks on the passage of the testicle into the scrotum during fetal life. This is commonly called the *descent* of the testis; but, as the writer observes, if we consider the ordinary position of the fetus in utero, this term is obviously incorrect:—

"Between the fifth and sixth month of fetal existence—sometimes later—the tes-

ticle begins to move from its situation near the kidney towards the ring, which it usually reaches about the seventh month. During the eighth month it generally traverses the inguinal canal, and by the end of the ninth arrives at the bottom of the scrotum, in which situation it is commonly found at birth. The testicle, both during its passage to the ring and through the inguinal canal, carries along with it its original peritoneal coat, adhering by the reflexion of this membrane, during the whole of its course to the parts behind, in the same manner as whilst situated below the kidney. The testicle, therefore, does not pass directly and abruptly into a pouch prepared to receive it, but carries the peritoneum with it, continuing to be connected to the parts behind by the reflexion of the membrane, between the folds of which the vessels and nerves join the gland. In the passage of the testicle from the abdomen to the bottom of the scrotum, the gubernaculum, including its peritoneal investment and muscular fibres, undergoes the same change as that which takes place in certain of the *rodentia* at the access of the season of sexual excitement; the muscle of the testicle is gradually everted, until, when transition is completed, it forms a muscular envelope external to the process of peritoneum, which surrounds the gland and front of the cord. As the testicle approaches the bottom of the scrotum, the gubernaculum diminishes in size, owing to a change in the disposition of its areolar elements: the muscular fibres, however, undergo little or no diminution, and are very distinct around the tunica vaginalis in the recently descended testicle. The mass composing the central part of the gubernaculum, which is so soft, lax, and yielding, as in every way to facilitate these changes, becomes gradually diffused, and after the arrival of the testicle in the scrotum, contributes to form the loose areolar tissue which afterwards exists so abundantly in this part; the middle attachment of the gubernaculum, which may be traced to the dartos at the bottom of the scrotum, gradually wastes away, and soon becomes indistinct, though slight traces of this process often remain to the latest period of life. Thus, after death, in dragging the testicle of an adult out of the scrotum, by pulling the cord, the lower part of the gland, which is uncovered by serous membrane, is often found connected to the bottom of the scrotum by a band of firm and dense areolar tissue, which requires division with the scalpel. This band is the remains of the middle attachment of the gubernaculum" (p. 963).

In the section on the Abnormal ana-

atomy of the Testicle we have a very carefully digested essay, and one which will well repay the pathological student by its perusal. We know of no English surgeon better qualified to deal with this subject than Mr. Curling, and accordingly we find in the various paragraphs the condensed experience of an acute observer. Under the head of a normal anatomy the writer treats of congenital imperfections and malformations,—deficiencies of the vas deferens,—imperfect transition,—inversion,—atrophy, and arrest of development,—wasting,—hydrocele in its various forms and complications as it affects the testicle and spermatic cord,—hematocele, orchitis,—carcinoma,—cystic disease,—calcific deposits,—and varicocele. Among these subjects we find one of peculiar interest to the surgeon, because it is but little known, and we do not remember to have seen it described by any other writer: we allude to "*Inversion of the Testicle.*" Mr. Curling says—

"It sometimes happens that the position of the testicle in the scrotum is reversed, so that the free surface presents posteriorly, and the epididymis is attached to the anterior part of the gland, instead of to the posterior. The first case that I met with was that of a man who had a swelling of the right testicle, which puzzled his medical attendant. On examination I found this to be the epididymis thickened from chronic inflammation. I was able easily to trace the vas deferens proceeding to it along the front of the scrotum. The body of the testicle was unaffected, and its posterior edge was quite smooth and regular. The disposition of the left testicle was normal. On visiting the Hôpital de Midi in Paris, in April, 1849, M. Ricord showed me a case of epididymitis on the left side, in which the gland was thus inverted. He informed me that he had often met with this arrangement. I have since had two patients under my care, one of whose testicles was thus inverted. One was a lad in the London Hospital affected with epididymitis: the other was a gentleman who consulted me for chronic orchitis confined to the body of the testicle. The epididymis being unaffected, the inversion was less perceptible than in the three preceding cases. M. Maisonneuve, in a thesis published in Paris in 1835, I believe first called attention to this irregular disposition, which he states that he had met with many times upon the dead body, and upon the living; and he mentions what I remarked myself in the four cases just noticed, that the inversion was confined to one side.

Surgeons should bear in mind the liability to this disposition of the gland in making their diagnosis of the diseases affecting it" (p. 991).

The remarks, at page 998, on the frequent existence of spermatozoa in the fluid contents of the cysts of hydrocele are well worthy of perusal.

This article is brought to a conclusion by an account of the morbid anatomy of the scrotum, in which the subjects chiefly discussed are elephantiasis and cancer scroti. It will be perceived from this description that no part of surgical pathology which can throw light upon the diseases of the testicle and its appendages has escaped the author's notice. Of *cancer scroti* Mr. Curling observes that it

"occurs more commonly at the middle period than at any other time of life. In the majority of cases which I have met with, the disease occurred between the ages of thirty and forty. Those exposed, however, to the action of soot may become affected at a much earlier period. Mr. Wedd has figured a diseased prepucce and soot-wart on the scrotum from a boy aged fifteen; and Sir J. Earle witnessed a case of the disease as early as at eight years of age. It appears that the seeds of this malady are sown in early life, but in general do not germinate until they have remained for some time dormant in the system. What is the permanent effect on the scrotum produced by soot which thus renders it in certain individuals so peculiarly susceptible of a cancerous action at some distant period, we cannot explain; but that the soot, though the exciting cause of the disease, may in some instances be a remote one, is shown by several striking facts. It is known that persons who have been sweeps when young, but have abandoned the occupation, have afterwards been attacked with chimney-sweeper's cancer, although they have long been removed from all contact with soot. A sailor, between forty and fifty years of age, was admitted into the London Hospital with an ulcerated sore on the scrotum, presenting all the characters of genuine chimney-sweeper's cancer. The inguinal glands were indurated and enlarged, and subsequently ulcerated. He had been brought up as a sweep; but for the last twenty-two years, during which period he had served at sea, he had not been employed amongst soot in any way whatever. The disease first appeared in the scrotum about three years before. In this case, therefore, the injurious influence of soot must have been exerted nineteen years before the appear-

ance of disease, during which long period he was entirely recovered from the effects of its exciting cause. It has admitted happened after the morbid parts had been completely extirpated, and the wound healed, the patient having avoided further contact with soot, that the disease has reappeared as it were afresh, a second, and even a third time; not, however, in the matrix of the wound, but on a detached part of the scrotum. These, and similar facts, lead to the conclusion, that though abandonment of his occupation may render the adult chimney-sweep less liable to cancer, it by no means forms a satisfactory security against its occurrence." (p. 1016).

The *Anatomy of the Thorax*, by Dr. R. Hutchinson, is an article of considerable extent: it covers upwards of seventy closely-printed pages; and, while it commences in Part XXXVIII, it occupies nearly one-half of Part XXXIX. In this elaborate essay Dr. Hutchinson gives us, in the first place, an account of the different varieties of respiration in animals, and the structure of the thorax, as well as the circumstances which affect the conformation of the cavity. A curious series of engravings is here introduced, showing the exact space of the thoracic cavity, encompassed by each pair of ribs respectively. The reader will also find many tables and calculations, showing the relation of the external chest to the height or stature of individuals. After a very full description of the bony cavity, we come to the muscular parietes, and the circumstances which govern the motion of the ribs. The author goes into a minute description of the changes produced by respiration in the thoracic cavity, and illustrates his views by numerous wood engravings on the lever-action of the ribs. The various conditions which modify the act of respiration, its influence on position, the form of the thorax, the pulse, and other physiological states, are also fully described.

The two following articles, on the *Thymus* and *Thyroid Glands*, are from the pen of Dr. Handfield Jones, an indefatigable pathologist, who has contributed many valuable papers to the pages of this journal. The human and comparative anatomy of these ductless glands is given with sufficient minuteness and care to put the reader on a level with all that has been hitherto ascertained with respect to them. After remarking that, owing to the conditions

which chiefly affect the size and repletion of the *thymus gland*, it must be regarded as a very exact exponent of the state of the intricate processes generally, or a delicate barometer of nutrition, Dr. Jones gives us the following speculation respecting its probable function in the economy:

"Now if one of the organs which belong to the class of ductless glands have for its function to act as a living attractive recipient or reservoir for the blood as mass, may not another fulfil its destined purpose by leaving as a medium for that part of the blood which ministers to nutrition, perhaps for the plastic element of the liquor sanguinis, in particular? When such plastic material is in superabundance in the circulating current, a quantity of it passes off, and solidifying in the thymic cavities, assumes that most universal of all organized forms, the form of nuclei. When there is again a demand for such material, the solidified particles would again liquefy, and re-enter the impoverished blood. It is not difficult to understand that such a function may be most necessary during the period when growth is most active, the supplies of nourishment most frequent, and the waste of the tissues most rapid; but that as the several nutrient processes, both of the assimilative and destructive kind, attain to more steadiness and equilibrium, diminishing somewhat in their intensity and rapidity, but increasing in real strength, firmness, stability, and perfection (one is obliged to use somewhat metaphorical language); it may no longer be requisite, and the organ will therefore undergo a gradual atrophy." (p. 1101.)

Of the use of the secretion of the *thymus gland* physiologists are at present unable to give any satisfactory explanation. Dr. Jones quotes Mr. Simon's view, that this organ serves as a diverticulum to the cerebral circulation; but, as he justly observes, further investigations are required before this can be received as a true solution of the physiological difficulty.

In the section on the *Thyroid*, Dr. Jones devotes a short space to an account of its morbid anatomy, and the alterations of structure which the gland undergoes.

Passing over a short article on the *Tibio-fibular Articulation*, by Dr. M'Dowal, we come to an essay on the *Tongue*, by Mr. H. H. Salter. The human anatomy of this organ, including the microscopic characters of its muscular fibres, are well described, and illus-

trated by the aid of wood-engraving. The 39th Part closes with the account of the papillary structure of the organ; and, in continuing the subject in the 40th Part, the author gives us a description of the comparative and morbid anatomy of the organ.

We next come to an admirably-written article, on the physiology of *Tæch*, from the pen of Dr. W. B. Carpenter. The author has shown great care in the preparation of this paper, and has duly noticed the observations and discoveries of Weber, and other physiologists. It is not commonly known to what degree the sense of temperature is influenced by the extent of surface on which the impression is made, or that the *left* hand is in most persons more sensible to variations of temperature than the right.

Every one is familiar with the fact that hot water in which a single finger may be held without inconvenience, will be felt intolerably scalding when the whole hand is immersed in it. And it has been shown by Professor Weber, that if one vessel of water be heated to 98° and another to 104°, and the whole of the hand be immersed in the former, while the finger alone is immersed in the latter, a wrong judgment of their relative temperatures will be probably given, that which is really the cooler being pronounced the hotter, on account of the larger extent of surface on which it acts. This mistake was made in some of his experiments, when the difference was as small as eight degrees, the cooler water being at 98°, and the hotter at 106°, and yet the former being esteemed the hotter. So, again, the immersion of the entire hand enables minute differences of temperature to be detected, which could not be recognised by the immersion of a single finger.

By the former method, a difference of only one-third of a degree may be distinguished; the entire hand being immersed, repeatedly and successively, in two vessels of water, differing only that much in their relative warmth. But it is remarked by Professor Weber, that these minute differences are best detected when the medium examined does not fall short of, or exceed very considerably, the usual temperature of the body; just as the ear can best perceive a difference of tone in sounds which are neither very acute or very grave.

It is a remarkable fact, discovered by Professor Weber, that the left hand is in most persons more sensible to variations of temperature than the right. Thus, when the hands of a person lying in bed, and

having exactly the same temperature, are plunged simultaneously in separate vessels of hot water, the left hand is believed to be in the hotter medium, although the water in which it is immersed is really one or two degrees colder than the other. This difference is the more remarkable, as the power of tactile discrimination is usually greater in the right hand; and it is attributed by Professor Weber to a difference in the thickness of the epidermis, the left hand usually having a thinner epidermis than the right, especially in the palm, because it is less used. But this will only apply to the hand; and since (as will be presently shown) we possess a greater power of discriminating warmth through the entire surface of the left side than through that of the right, it would seem much more probable that there is an original difference in the tactile endowment of the two sides respectively. (p. 117.)

The section on the *Improbability of the Sense of Touch* will be found especially interesting in reference to the education of the blind.

The two remaining articles are entitled *Tæchæ* and *Ostrææ*. Of the former, which is by Mr. A. R. Jones, we shall only remark that it is a very learned essay on the general and minute anatomy of molluscous animals; while the latter is the commencement of an article important to the practical anatomist and surgeon, from the pen of Mr. John Adams. The present part contains only the account of the anatomy of the urethra in the male—its length, direction, and structure. We shall reserve our opinion of it until the appearance of the next part, which is promised for November.

Whatever objections may be made to certain serial publications on the ground of want of punctuality, we do not think that they can be fairly applied to the *Cyclopædia of Anatomy and Physiology*. Any one part shows that it has required immense labour and industry for its preparation; and it is highly creditable to the editor and contributors that, without impairing the value of the articles, the parts have appeared at such comparatively short intervals. In our next notice we hope to be able to announce the completion of one of the most valuable works on anatomy and physiology in the English language.

Physician and Patient; or a Practical View of the Mutual Duties, Relations, and Interests of the Medical Profession and the Community: From the text of WILLIAM HOOKER, M.D. Edited by EDWARD BENTLEY, M.D. &c. Small 8vo. pp. 303. London: Bentley. 1890.

THE topics discussed in this little work are:—

1. The uncertainty of medicine; its causes and its extent.

2. Skill in medicine; in which are shown the advantages of the possession of comprehensive principles, and the careful investigation of every circumstance connected with each case.

3. *Popular errors.* In this section the over-estimating the value of remedies is exposed, and the important truth expounded "that it takes as much knowledge to know what not to do, as it does to know what to do." It is also here shown how "those who drug their patients freely are more apt to satisfy the mass of the community than those who place reliance upon positive medication."

4. *Quackery*; the consideration of which embraces homœopathy, popular medical literature, hydropathy, &c.

5. Good and bad practice. The incompetence of the public to judge between these, the frequent success of ignorance and loud-talking assumption, are herein set forth.

We quote the points of distinction which the author gives between the *good and bad practitioner*. The skilful physician has—

"1. A less (smaller?) number of fatal cases in proportion to the whole number that come under treatment.

"2. A less number of bad cases, because he avoids converting light cases into grave ones, and succeeds in arresting disease in many cases in its very commencement.

"3. His patients have commonly shorter sicknesses.

"4. They are in a better condition after they have recovered, less apt to have bad results left behind, and less liable to disease in future.

"5. He has a less number of patients, and a smaller amount of sickness, in the same number of families."

These statements are undoubtedly true of the skilful physician, and they are also the test of his uprightness; for the man of honourable principles is

often put in contemptible comparison with the man of drugs and "medical manoeuvring," and will probably have to submit to present disadvantage in the comparison by those incapable of seeing through the frauds of the latter.

6. Theory and observation; their use and abuse.

7. Popular estimates of physicians. "There is no class of men (observes the author) whose talents and attainments are so erroneously estimated by the public as those of physicians." Of the truth of this statement daily experience must convince any one; and the most sanguine beginner in practice, albeit the most competent of all men, may live to find that he has never been duly appreciated by a "discerning public."

8. Intercourse of physicians. We could desire that a large proportion of the profession would carefully study and act upon the contents of this chapter. More harmony and less jealousy would ensue. The editor subjoins the American code of medical ethics, which, however, we may notice, is compiled in the main from "Percival's Medical Ethics." 9. Interference with physicians. The public may read this chapter with advantage. 10. Mental influence of mind and body in disease. 11. Influence of hope in the treatment of disease. 12. Truth in our intercourse with the sick. 13. Moral influence of physicians.

These four chapters involve the discussion of subjects closely allied, and of the very first importance to every conscientious practitioner.

The last chapter (14) treats of the trials and pleasures of a medical life. We receive it as a wise dispensation that the pleasures come first, and that the pains follow. No pleasure in a medical after-life can be put in competition with the delight which attends the incessant acquisition of fresh knowledge experienced during the diligent employment of the period of preliminary and hospital studies. Many would otherwise be deterred from encountering only toil, anxiety, and too often ingratitude, from "those upon whom they have conferred the highest favours." That "there is not as much gratitude in the world as is commonly supposed," and that "there is often much show of gratitude, but it is seldom, though sometimes, more than mere show," are truths which experience soon teaches. A higher

motive than that of the mere hope of reward is required for the performance of our duties, or they must be irksome indeed. After all, perhaps, it may be as well that we should, when smarting under the ingratitude of patients, put the inquiry to ourselves, whether we are as grateful as we should be to the Giver of all Good, and whether we have really made the best use of the "talents" which He has entrusted to our charge.

Dr. Hooper's treatise is very comprehensive, as will have been perceived from the preceding summary of its contents. Dr. Bentley, in editing it, has judiciously exercised the power of abridgment and condensation. To all interested in the discussion of the ethical relations of the profession, (and who among us is not interested therein?) we doubt not that it will prove acceptable.

On the Development of the Retina and Optic Nerve, and of the Membranous Labyrinth and Auditory Nerve. By HENRY GRAY, M.R.C.S. From the Philosophical Transactions. 4to. pp. 12, and Plates. London: Taylor. 1850.

THIS memoir demonstrates the mode of evolution of the essential parts of the visual and auditory apparatus. The author states, that so far as he is acquainted, many of his observations have not been made before; at the same time that they confirm the account given of the structure of these parts in his *Prize Essay on the Anatomy and Physiology of the Nerves of the Human Eye*, contained in the library of the College of Surgeons, but unpublished.

Mr. Gray traces the development of these organs from their first appearance in the anterior cephalic cell, at the thirty-third hour of incubation, up to its condition on the seventh day. Hence he concludes that the retina is originally a protrusion from the anterior cephalic cell, being hollow, and communicating with its cavity, becoming separated from its parent cell in proportion as the brain is developed, until it comes into relation with other parts of the visual apparatus, as described in this memoir.

In like manner the author traces the membranous labyrinth and auditory nerve to be a protruded portion of brain modified to adapt it for its particular connections and functions; thus,

"The membranous labyrinth, like the retina, is a protruded portion of the brain, being hollow, and communicating with the ventricular cavity from which it arises. As the progressive development of the brain proceeds, the auditory sac becomes more elongated and of a pyriform shape, the dilated portion being analogous to the vestibule, the contracted subular portion to the auditory nerve; this subsequently becomes solid, and the cavity in the vestibule does not communicate with the ventricle from the wall of which it is an offset" (p. 12).

The several steps of the development of these organs are illustrated by steel engravings. The entire paper reflects credit upon the author's industry and accuracy as an observer.

A REMARKABLE CASE OF PHOTOPHIA.

THE patient was a nervous, excitable lady, thirty-eight years of age; tall and thin, of an active temper, and possessing a strong understanding. She had suffered frequently from hysterical pains, flatulency, &c. and tape-worms. The patient first complained of weakness of the eyes in reading, &c. with *musca volitantes* and intolerance of light. She became very anxious on this account, fearing amaurosis. The eye showed nothing unusual but that the iris was rather less contractile than natural. Soon afterwards, photopsia followed; sparks and flashes of light constantly followed. Neither day-light nor candle-light could be borne, and lastly any degree of light caused such intense pain, that the room was kept entirely darkened, everything of a light colour was removed, the plates, spoons, &c. were changed for articles made of dark brown wood. Every object seemed to glow with a bright light, a continual fire appeared to her on all sides, suns seemed to glare above and below, from which she could not withdraw her regard, the whole street appeared in full glow, though three or four folds of curtain hung before the windows. Sleep was entirely absent; the night was passed in anguish, the day in delirium, so that it was clear, that not only the retina, but that the brain also, was the seat of the disease, which produced the optical delusions. The pulse was generally quick, the tongue was clean, the digestive functions unimpaired. This condition lasted for eight weeks with some little amendment. The symptoms then gradually subsided. With the aid of blue spectacles light became tolerable. Sedatives, antispasmodics, counter-irritation, were employed in the treatment of this case.—*Casper's Wochenschrift*, x

Proceedings of Societies.

ACADEMY OF MEDICINE, PARIS.

Oct. 7, 1880.

Influence of Ergot of Rye on Fetal Life.

M. DANYAU (in the name of a commission composed of MM. Orfila, Adelon, Villeneuve, Merat, and Danyau) read a report in answer to a letter from the Prefect of the Seine, which therein sought the opinion of the Academy on the following question:—"What may be the influence of ergot of rye on the lives of infants, and on the maternal health?" This officer having observed an almost regular annual increase in the number of still-born children, and having been informed on medical authority that in a large number of these cases ergot of rye had been administered during labour, he was struck with the coincidence. Having also learnt that the same drug is extensively employed to produce abortion, he had thought it advisable to consult the Academy before having recourse to any stringent measures with a view to putting a stop to these evils.

It was also submitted whether it is not desirable that the use of ergot should be forbidden to midwives, and that, by means of the medical press, greater prudence in its employment should be urged upon practitioners.

The reporters observed that ergot should be used only, where to facilitate labour, the pelvis being large, the soft parts well formed, an inflammatory state absent, the dimensions and position of the fetus normal, the os uteri dilated and soft, the perineum not offering rigidity,—the labour is prolonged from no other cause than the insufficiency of the uterine contractions. The reporters point out the evil consequences of the violation of these conditions, and state instances of the rash employment of ergot where one or more of them have been wanting or reversed. No careful or skilful practitioner, observe the reporters, will administer this drug until having satisfied themselves that all circumstances are favourable, and that other and simpler measures have failed, nor lose sight of the fact that the contractions induced by ergot are of a tetanic character, and capable of suspending the utero-placental circulation, thereby inducing a state of asphyxia more or less complete. The state of the fetal circulation after the administration of ergot affords an indication whether the labour should be permitted to be concluded by the uterine contractions or be terminated by

the forceps. If the fetal pulsations become either unusually frequent or slow, and at the same time irregular and feeble, the reporters state that the moment is arrived for extraction, and that to leave the case to the expulsive powers of the uterus would be attended with fatal results.

With due precaution, under the vigilant control of a practised ear, the dose of ergot being moderate (i. e. 2 or 3 grammes, = 30-45 grs. R&G), given at intervals of twenty minutes, or half an hour, the reporters pronounce that ergot may be given with safety to the fetus. The period of safety, however, is not of long duration; at most two hours; frequently one hour's duration of the labour under the full influence of the drug is sufficient to produce evil effects; the practitioner should therefore be capable and fully prepared to extract without loss of time.

To the appreciation of all these circumstances, and the adoption of the appropriate and judicious measures, midwives are incompetent; by readiness and ignorance they therefore often cause still-births, or, where sensible of the condition of the patient, they send for medical assistance, much valuable time for action is lost.

With reference to the second question—viz. the influence of ergot on the maternal health—the report states that with a few exceptional cases no decidedly poisonous influences have been shown to be exerted by its obstetric administration. At the same time the report notices the accidents that have ensued to the mother from its improper or ill-timed exhibition, e. g. rupture of the uterus, and laceration of the vagina and perineum, the last being more frequently met with now, than formerly.

The reporters state, that entire liberty of action must be left to midwives for the administration of ergot in cases of post-partum hemorrhage. They speak in the strongest terms of praise of the advantages of full doses promptly given when hemorrhage occurs after delivery, or even when administered a short time before birth, in cases where flooding may be anticipated. To give permission, on the one hand, to midwives, and to refuse it on the other, is obviously attended, as the reporters observe, with great difficulty, and must be the source of uncertainty. The only course which remains is to inculcate thoroughly the principles which should guide their conduct in its use, and control their practice.

The reporters add, with regard to the production of abortion by ergot, that there is no reason to believe that it is capable of influencing uterine contractions before the full period, unless they have been previously excited by some other means.

The reporters express regret that there exist no means of preventing the employment of those means of exciting uterine contractions, and the subsequent administration of ergot, for criminal purposes. For the determination of the direct effects of the drug, thus used, on the maternal health, facts (the reporters remark) are wanting.

The Report closes with the following conclusions:—

1. Ergot of rye, administered imprudently, causes death to the fetus and injury to the mother.

2. That in the present state of the law it is not possible to interdict the use of ergot by midwives, and that its interdiction would in some cases be attended with serious disadvantages.

3. That it is desirable to increase the education of midwives, and strictly to define their duties.

4. That the Academy, not having any control over the medical press, cannot compel the publication of the precautions suggested by the minister; but confines itself to the publication, in the medical journals, of those parts of the Report which seem calculated to answer the same purpose.

The Report was adopted after a short discussion. It was supported by MM. Moreau, Velpeau, Gibert, and Rochoux; and opposed by M. Gerdy.

ACADEMY OF SCIENCES, PARIS.

On the Employment of Mercurials in the Treatment of Typhus Fever. By M. BROQUELLE.

IN 1847 M. Serres presented to the Institute a series of communications tending to throw light on the nature and treatment of typhus fever. M. Serres was desirous of more particularly calling the attention of the medical world to two points in the history of this disease, at the same time pointing out a new mode of healing intended to prevent the formidable accidents, to moderate the most dangerous symptoms, and, lastly, to convert the severest form of typhus into a disease of a much milder character. Having been appointed by the hospital administration to replace M. Serres provisionally at the Hôpital de la Pitié, I thought I could not do better than continue the mode of treatment he had adopted with regard to typhus fever, and submit it to a new course of experiments. It is the result of this treatment that I now submit to the judgment of the Academy.

It will be as well here to recall in what

the mode of treatment adopted by M. Serres consisted, and the results which he obtained. The treatment by means of mercurials consisted in the employment of the black sulphuret of mercury (ethiops mineral) internally, in doses which varied from gr. 0.60 to 2 grammes,* and in the external application of mercurial ointment (Neapolitan ointment), by means of friction on the abdomen, in doses varying from 15 to 30 grammes daily: this treatment was continued eight, ten, twelve days, or even for a longer period, until the cessation of the characteristic symptoms of the disease. The results of this treatment were thus announced by M. Serres to the Institute:—The employment of black sulphuret of mercury in the doses above mentioned might be continued for eight, ten, or twelve days, without salivation being produced; and at the end of this time, whenever salivation was produced, it never manifested itself with such intensity as to cause any bad results to be apprehended.

The result of the mercurial frictions on the abdomen was the immediate disappearing of the red spots, and the rapid subsiding of the swelling. Under the combined influence of these two means the diarrhoea was modified; the frequency of the pulse considerably diminished; the fever subsided; the headache and the delirium were much relieved. The duration of the disease was not much shortened; it usually existed about the ordinary period, for three or four weeks; but it passed off without any serious consequences, and especially without the adynamic form of typhus becoming very severe. Such is an abridged description of the conclusions arrived at by M. Serres. Before giving any account of the results which I have obtained in fifteen cases of typhus fever, all very serious cases, and submitted to the above treatment, I should state that I have rigorously followed the formula adopted by M. Serres, and that the therapeutic results obtained, which have even been more successful than those of M. Serres, cannot be attributed to any other source.

The black sulphuret of mercury was given to the patients on their entrance into the hospital. The dose was at first one gramme daily, in powders or in pills, made up with mucilage. This dose was given five or six times. If no improvement took place at the end of two or three days, the dose was increased up to 1½ gramme, or even to 2 grammes; but this quantity was never exceeded. The employment of the sulphuret was suspended as soon as the patient showed signs of convalescence: in no case were the symptoms of salivation so

* One gramme is equal to about fifteen grains

strong as to require premature suspension of the treatment.

The frictions on the abdomen with mercurial ointment bore relation to the quantity of sulphuret internally exhibited; with 1 gramme of sulphuret 16 grammes of ointment were prescribed to be applied at two frictions, with the application of poultices, to facilitate the absorption; with 1½ grammes of black sulphuret 24 grammes of ointment; and with 2 grammes of sulphuret 30 grammes of ointment were applied, each at three frictions. Every other day the abdomen was well cleaned with soap, to facilitate the absorption of the ointment.

The additional means employed were, 1, ice, Seltzer water, lemonade; 2, simple or slightly laxative enemata when any constipation existed; 3, in the intermittent form of the disease, of which there were four cases, I gave, in addition to the sulphuret, 0.25 to 0.30 grammes of musk daily. This was discontinued when the delirium and agitation diminished. Fifteen patients, labouring under severe attacks of typhus fever, were submitted to the above treatment; of these ten were men, and five were women: the ten men were of the respective ages of 16, 18, 20, 22, and 36 years; the women 15, 18, 20, 21, respectively.

The ten men were attacked with typhus fever presenting the following forms:—four, the ordinary abdominal form, with stupor, headache, &c.; five, the most severe adynamic form; one, the intermittent form, with delirium and violent agitation. The five women presented two cases of the intermittent form; one of the intermittent adynamic form; and one the adynamic form alone; and one the ordinary abdominal form. These fifteen patients had all been a certain time in a more or less severe state of suffering previous to admission into the hospital. In each case the treatment was commenced on the day after their admission. The following is an account of the effects produced on the principal symptoms, and on the ensemble of the disease:—

Fever.—Under the influence of the first doses of the black sulphuret, and the first frictions, the skin became less hot and dry, and in some cases was slightly moist from perspiration. At the same time, the pulse diminished in strength and frequency: this effect also was produced in the only case which terminated fatally in consequence of intestinal perforation.

The tongue, at first dry and rough, and the gums and lips of a sooty colour, did not lose their characteristics until salivation supervened. Salivation occurred in twelve cases; nine were produced in two cases which were equally as well cured: in

each of these two cases the tongue remained quite dry until the fever ceased. In the case of intestinal perforation the tongue remained dry throughout. In the twelve cases in which salivation was produced it took place in two cases on the sixth day of treatment; in three cases on the seventh; in four cases on the eighth; in one case on the twelfth; and in the other case on the thirteenth day. Except in one case where the salivation and swelling of the gums took twelve days to remove, and was very considerable, it was in all the others slight, and of but little importance. In every other case it did not continue more than four or five days, and required no particular treatment.

As for the salivation, the following propositions may be considered as established:

—1. In the case of ordinary typhus fever of moderate severity, salivation shows itself more rapidly: it is stronger, and continues longer during convalescence. In general, it announces the approaching arrival of convalescence. 2. In the most severe cases, salivation takes longer time to produce: it is generally less intense, and continues no longer than the first days of convalescence: it precedes by a few days the cessation of the fever, and constitutes a sign of approaching restoration to health. Sometimes, however, it does not appear until the entire cessation of the febrile symptoms. 3. In the extremely severe cases salivation is with great difficulty produced; and as long as it does not arrive, more or less dangerous consequences may be feared. In such a case we must not be discouraged, but continue for a longer period increased doses of the sulphuret and the mercurial frictions. 4. In some cases of moderate severity salivation does not occur at all. In each of the fifteen cases the treatment was always continued, not only up to the appearance of the salivation, but up to the time of the cessation of fever, and the amelioration of all the symptoms.

The swelling of the abdomen, except in the case of intestinal perforation, has constantly diminished with great rapidity, and that from the commencement of the treatment: it is to the combined influence of the employment of sulphuret and mercurial ointment frictions that the result must be attributed.

As to the *stools*, out of the fifteen patients there was constipation in two cases, which enemata alone were able to remove: the sulphuret was without effect in removing it. In two other cases the sulphuret produced diarrhoea, which did not previously exist, and which, since its employment, induced one or two liquid stools daily. In three cases the characteristic diarrhoea which occurred on their admission sensibly

diminished action as a few doses of sulphuret were taken. In eight cases the diarrhoea neither increased nor diminished: it took its course, and diminished only at the same time that the other characteristic symptoms of the disease abated.

In every case the mercurial frictions were made on the abdomen, the red spots disappearing in the space of 24 to 36 hours; no others appeared but those which occupied the base of the thorax, on the breast, or elsewhere.

As to headache, no particular effect was remarkable in either of the cases; in fact, it did not constitute any leading feature.

In three cases where violent delirium existed (infopatientia) from 26 to 30 centigrammes of musk was combined with the black sulphuret, and this dose continued until the cessation of the symptoms. In these four cases the improvement was rapid, and five days was the longest period in which it was found necessary to exhibit the musk in combination with the sulphuret. In one case it was found advisable to use cold water applications to the head; the delirium was very violent, and a strait waistcoat was applied.

As respect of stupor in the comatose state did not disappear until an improvement had manifested itself in the other symptoms; the sulphuret produces no immediate effect.

The same may be said of the cough, &c., and there were no apprehensions of any serious consequences to the chest. The patient must perhaps be excepted who fell a victim to intestinal perforation on the twentieth day of the disease, and who at his admission presented the characteristics of very intense bronchial engorgement.

On this symptom the mercurials acted only by the influence which they exercised on the ensemble of the disease. In no case were there any serious hemorrhages.

The duration of treatment was in four cases seven days, in three cases eight days, in one case nine days, in three cases ten days, and one each 11, 12, 15, 16, and 17 days respectively; the mean time was 10 days. The minimum quantity of black sulphuret employed for the whole treatment was 7 grammes, and the maximum 26 grammes; the minimum quantity of mercurial ointment employed was 112 grammes, and the maximum 360 grammes; the mean quantity was 18·30 of sulphuret, and 300 grammes of mercurial ointment.

The total duration of the disease varied from 12 to 23 days; the mean duration of the disease—that is to say, of the fever—was 16 days.

Duration of Convalescence.—In all the cases this was very simple, proceeding uninterruptedly, and without any relapse.

In the case of one woman attacked with a most intense adynamic fever, there was sloughing of the sacrum; which required a month to cicatrise. Omitting this case, and reckoning from the time of the cessation of the fever, the patients remained in the hospital from eight to twenty-three days.

On the Presence of Casein in the Blood.

M. PAVEN read a communication from MME. Natalis Guillot and Felix Leblanc, on the presence of casein in a soluble state in the blood during lactation.

MM. Demas and Ouhours had previously pointed out the presence of casein in a male patient, and had given an analysis. M. Demas endeavoured, but unsuccessfully, to detect the presence of casein in the blood of sheep during the time of suckling; but up to the present time no person had succeeded in isolating this product of the organism from the others which circulate with the blood in females during lactation. MM. Guillot and Leblanc have proved that the serum of the blood of two nurses on which they experimented, after having been deprived of albumen by heat and by filtration, furnished an abundant white precipitate when boiled with acetic acid. The quantity of casein appeared to bear a relation to the proportion of albumen contained in the serum. In the blood of new-born children they could not detect the presence of casein.

Hospital and Infirmary Reports.

KING'S COLLEGE HOSPITAL.

Excision of the Knee-joint.

THIS rare and formidable operation has lately been performed at King's College Hospital by Mr. Ferguson. We shall give a detailed account of the case, which has unfortunately terminated fatally.

The patient, who was a young man aged 21, had been in very good health until about three years ago, when he had a fall upon his left knee. In consequence of this the part became swollen and inflamed, and he was compelled to lie up, and undergo a course of treatment for some months, at the expiration of which period he was much relieved; but shortly afterwards the bad symptoms recurred, and he was obliged to submit to treatment again. About nine months ago he became crippled, and has been laid up since. As the disease of the knee-joint did not appear to decrease in severity, the surgeon under whose care he was in the country considered that ampu-

tation would be necessary, and for this purpose he sent him to the hospital, to be placed under Mr. Ferguson's care.

On examination the knee was found to be in the following condition:—It was enlarged to some extent, being about two inches more in circumference than the other. The limb was kept in nearly a straight position, and the patient could not alter this. When the articulating surfaces of the joint were pressed together, considerable pain was experienced; but if the part were kept perfectly quiet the patient suffered comparatively little pain. The skin was entire, and there were no ulcerations or sinuses; but the existence of several cicatrices evidently showed that the integument had been considerably involved at one period: the leg below was not wasted to any extent. The general health of the patient was neither weak nor robust; it was not so much influenced by the local disease as is frequently seen in such cases.

After having carefully examined this case, Mr. Ferguson gave it as his opinion that there was some serious disease at the knee-joint; but yet he did not consider that it was sufficiently bad, considering the patient's general health, to warrant the removal of the entire limb. He, however, thought that it was a very fit opportunity to endeavour to remove the diseased parts, at the same time to save the limb more or less useful to the patient. In fact, he proposed to the patient that he should perform the operation of excision of the knee-joint, to which a ready assent was given.

On the 20th of July the man was brought into the theatre, and placed under the influence of chloroform. An incision was made on each side of the joints in a straight direction from each condyle of the femur to below the heads of the tibia and fibula. A transverse cut was now made across the front of the joint below the patella. The ligament was divided, and this, together with the bone, was then turned upwards; by this means the joint was fully exposed. The ligaments connecting the articulation were then divided, and the soft parts were cleared well away from around the lower extremity of the femur. A common saw was then carried across this bone just at the upper part of the condyles, and the section was rapidly made. The knife was then most cautiously used, and the soft parts were separated from the bone behind, and the latter was removed. After this was effected the soft tissues were well cleared away from around the upper part of the tibia and fibula, and the heads of these bones were removed. Several arteries bled freely, and it was necessary to use many ligatures. The wound was brought

together by means of sutures, and wet dressing was applied. The limb was placed in a box made for the purpose, which was furnished with a foot-board, and with lateral flaps, which could be closed or opened at pleasure.

On looking at the surfaces of the joint, they were found to be much diseased—deprived of their cartilage. A considerable quantity of pus escaped when Mr. Ferguson cut through the joint in the operation.

On the day after the operation the patient appeared to be doing well. There was a freedom from anxiety on the part of his countenance. He did not complain of pain in the wound. There had been some bleeding from it, which had been checked by cold water. The pulse is very rapid—180. He is taking beef-tea and milk.

22d.—He has had some attacks of shivering. His countenance is slightly mallow. His pulse still continues very quick: it is 160 in the minute. He has had no vomiting. He complains of some pain in the head. The respirations are very quick, but he has no cough.

26th.—Rigors have occurred from time to time, yet there is no very marked symptom to produce uneasiness, with the exception of the condition of the pulse: it is 168 in the minute. The respiration is also very rapid; but the tongue is perfectly clean and moist. He has no vomiting, and he takes his nourishment well.

28th.—He appears to be somewhat better than he has been. The pulse is not so rapid, and the wound, which was looking unhealthy, and was in a sloughing condition, looks better. Granulations of a florid colour are rising up on each side. Diarrhoea, however, has set in. To take detection of logwood after each liquid stool.

29th.—This patient rapidly sank at 1 this day, after having passed a very fair night. He had another severe rigor yesterday. The diarrhoea continued unchecked, and his pulse, which had diminished in frequency, became very rapid again. Some hæmorrhage took place from the wound the evening before death.

On a post-mortem examination of the body being made, the internal organs were first examined, but they were found to be in a perfectly healthy condition. The only abnormal appearance to be found was within the large intestine, at the situation of the sigmoid flexure of the colon. Here there was a well-marked patch of congestion, about the size of the palm of the hand: this most probably was the seat of the diarrhoea.

The femoral, epaenous, and iliac veins were next carefully turned up and examined; but there was not the least altera-

ties from a healthy condition. When the wound itself was examined, the cause of the symptoms and of death was then found. The lower part of the femur was deprived of its periosteum for about an inch and a half in extent. The portion of the periosteum which covered the bone above was very easily stripped off, and on doing this a large drop of pus was seen subjacent to the membrane. Several inches of the extremity of the bone was then removed; and on a perpendicular section being made through it, pus was found to be diffused both through its cancellated texture, and in its medullary cavity as well.

On looking into the substance of the head of the tibia the bone was found to be in a somewhat similar condition, although to a less extent.

Here, then, was the cause of the peculiar symptoms which appeared after the operation, and of the fatal termination which ensued. Acute or suppurative necrosis, the result of the injury done to the bone during the operation, destroyed the patient. That there was some serious mischief going on somewhere, was evident soon after the operation. One symptom alone caused uneasiness in the minds of those who watched the case, although it was a symptom by itself, and this was the excessive rapidity of pulse, which kept up, and even increased in frequency. There was no obvious explanation for this circumstance; there was no undue febrile excitement, no inflammation about the wound apparently, no erysipelas; the tongue was perfectly clean, and the patient took his nourishment well. This one circumstance, therefore, indicated coming mischief, as it almost certainly does. The surgeon may be nearly sure that something is going wrong, although general appearances are favourable, if after a severe operation the pulse beats with unusual rapidity, and especially if the frequency continues or increases, there being no obvious reason for it.

On the third day a new and formidable symptom, especially dreaded by the surgeon, showed itself—rigors occurred. It was now feared that inflammation of the veins had taken place, or that pus was being deposited in some of the important organs of the body. The rigors ceased for a time, and the pulse became somewhat less frequent, and it was hoped that the patient might rally; but these hopes were of short duration. Diarrhoea, a frequent concomitant of purulent depôts, set in, and rapidly ended the patient's life.

Acute necrosis of the bones, which have been sawn through in an excision or amputation is by no means of frequent occurrence; in fact, it may be looked upon as a

rarity. We do not remember, amongst the very numerous operations on bones that we have seen, to have witnessed a case where a fatal result has occurred from such a cause. It is one of those unfortunate events which are liable to happen after violence has been done to a bone, whether in operation or otherwise; but it is impossible to say whether its occurrence in this case was owing to the peculiar nature of the operation put in force, and whether it would not have equally occurred if simple amputation had been performed. We believe that it may have followed; for no more mischief was done by the saw in the excision than would have been necessary in an amputation. It would have been needful to saw through the substance of the bone either way; and, if the section had been made through the shaft of the bone itself, there would have been more likelihood of necrosis occurring; for every surgeon is aware that necrosis is more likely to attack the shafts than the extremities of long bones; and for this very reason an eminent surgeon has recommended that amputation of the thigh should be performed, if possible, through the condyles of the femur rather than at the lower third in the ordinary place.

We were sorry, but not surprised, to see, by referring to the September number of the Edinburgh Monthly Journal, that some very ill-natured and undignified remarks have been called forth by the occurrence of this operation, and by the unfortunate termination of the case. The ill-favoured and anonymous critic has the bad taste to preface his argument against this operation as follows:—

"In the *Lancet* of the 27th July a student complains of having been unable to witness an operation at King's College Hospital on the 20th of that month, from the area of the theatre being occupied by three and twenty surgeons. It now appears, from the "*Mirror of London Surgery*," that the object which had attracted this great congregation of doctors was to witness an excision of the knee-joint. We regret the occasion of such an assemblage, in the first place, on account of the patient, who, we believe, thereby lost a life which might probably have been saved; 2dly, on account of the practitioners, whose time, we think, might have been more profitably spent; and 3dly, on account of the science of surgery, which it seems to us has taken a step in the wrong direction."

We need make no comment upon a passage like this; but we find further on, that the critic, in order to prove the "inexpediency" of this operation, makes reference to two instances in which it was performed by Mr. Syme twenty years ago, one

of which patients died, whilst the other, although the operation was recovered from, "retained a limb which could not be considered superior to a wooden one, since it did not grow with the general growth of the frame, so that when the boy became a man there was a great disparity of length between the sound extremity and that which had been the subject of operation."

From these cases alone, then, the Edinburgh critic has come to a hasty and arbitrary conclusion respecting this operation. We must not suppose him, as he has ventured to give an opinion on this subject, to be ignorant of the cases in which other surgeons besides Mr. Syme have performed excision of the knee-joint.

The celebrated Park, of Liverpool, who is deservedly remembered for the introduction into British surgery of excision of carious joints, proposed and performed this operation on Hector McCaghen, aged 33, on the 2d of July, 1781. It completely succeeded; and the patient, who was a sailor, was actually enabled to follow his employment, as Park states; for, writing in 1789, eight years after the operation, he says:—"To the history of the case of Hector McCaghen there related I have now to add that he afterwards made several voyages to sea, in which he was able to go aloft with considerable agility, and to perform all the duties of a seaman; that he was twice shipwrecked, and suffered great hardships, without feeling any farther complaint in that limb; but was at last unfortunately drowned by the upsetting of a flat in the Mersey."

This case alone showed the expediency and benefit of the operation. By it the patient's life was saved, and the disease was extirpated, at the same time that a limb much more useful than any artificial substitute could possibly be was preserved, and must have been eminently serviceable to enable the man to follow such a laborious pursuit as that of a sailor.

Sir Phillip Crampton also performed excision of the knee-joint in two instances. Both recovered from the effects of the operation, although one of the patients died from general exhaustion three years and a half afterwards; the other case terminated most happily: so that Sir Phillip Crampton, after having examined the patient upwards of three years afterwards, was enabled to make the following report:—"She is now in town; and I have this day (November 3, 1826) examined the limb, and find that the femur and tibia are firmly consolidated; the leg and thigh are not in the slightest degree wasted; but the limb is considerably bowed outwards. She wears a shoe with a cork sole four inches thick; and, to use her own ex-pression,

is able to stand or walk the length of a day."

In other few instances also this operation has been performed, and with a certain amount of success. Therefore, it would have been more liberal and more fair had the critic in the Edinburgh Monthly Journal referred his readers to the cases of Park and Crampton, which turned out so successfully, and not have contented himself with measuring the expediency or the success of this operation by the two cases of Mr. Syme.

It is laudable on the part of a surgeon to attempt the removal of disease, and the salvation of a limb at the same time, by excising the affected joint; but an operation of this nature cannot be undertaken without placing the patient in a certain amount of danger, any more than when a whole member is amputated. It is true that, generally speaking, the excision of the elbow and shoulder-joints are more likely to be less fatal than removal of the corresponding limbs: at the same time, our own observation has shown us that they are not free from danger, and that possibly recovery might have taken place if amputation had been performed instead of the more protracted operation of excision: nevertheless, we should not refuse to undertake this latter proceeding in a fitting case. It is not to be denied that a large joint like the knee cannot be excised without considerable hazard to the life of the patient. It is impossible also to tell beforehand what will be the result of a simple amputation of the thigh: death may ensue after either. If, however, recovery takes place, the patient in the one case still has a useful limb, whilst in the other he only retains an artificial substitute, which would not certainly permit him to follow the laborious avocation of a sailor.

Notwithstanding, therefore, the denunciation of the Edinburgh critic, it is a question for serious consideration whether the surgeon is not acting wisely in certain instances in attempting to save a leg by excision of the knee-joint. If the advantages and disadvantages of the operation are placed before the patient, and he is willing to undergo it, the surgeon is certainly justified in doing so.

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 11th inst.:—Messrs. S. Henson—J. W. Baker—G. Harley—J. W. Walker—W. Browne—H. A. Aldred—T. S. Holland—W. Heron.

Medical Trials and Inquests.**CHELMSFORD COUNTY COURT.**

October 2, 1860.

*Before W. Gardon, Esq., M.A., Judge,***ACTION FOR RECOVERY OF CHARGES IN ATTENDING AS A PHYSICIAN.***Octavius Pritchard v. Maria Warmington.*

THIS action (which was tried by a jury) was for £25. 4s. for medical attendance and prescriptions for the defendant, at Hylands, the seat of J. Attwood, Esq., with whom she lives as housekeeper. The case was watched with much interest by the medical profession, a large number of whom from the town and neighbourhood were present.

Mr. DUFFIELD represented the plaintiff, and Mr. DURRANT the defendant, who had paid £12. of the sum claimed into Court.

It appeared from the evidence of Dr. Pritchard, who practises in Chelmsford as a consulting surgeon, under a Scotch diploma, that he had attended the defendant occasionally at her own request from March, 1847, to the month of May in the present year; but in April, 1847, a settlement took place, and the plaintiff's charge (five guineas, for about the same number of visits) was paid by the defendant without objection. By this payment, it was urged on the part of the plaintiff, that the defendant had admitted the reasonableness of the charge, and bound herself in a contract to pay after the same rate the present bill, which was for attendance extending over a period of three years. The total number of visits had been thirty-two, but certain deductions were made by the plaintiff, on account of his having on some occasions been sent for without expense of hire. The bill thus reduced was presented in May last, since which time the plaintiff, annoyed at the objections which had been made to it, had ceased to attend the defendant.

For the defence it was stated that the first account for £5. was for ten visits, and that therefore the plaintiff was only entitled to 10s. a journey on the present amount. His qualification as consulting surgeon was also disputed; and no less than six members of the profession, resident in Chelmsford, were called to prove their usual charges under similar circumstances. Some of them considered that 7s. for each visit (without the preparation of medicine) was an adequate remuneration; while another thought 10s. would not be too much; and the last gentleman called (Dr. Bird), who has been since attending

Miss Warmington, was of opinion, for a person of long standing and experience in the profession, a guinea for each journey would be only a fair remuneration.

His Honour carefully and at great length summed up the evidence, leaving it for the jury to give a verdict for the amount claimed, if they were of opinion that a guinea per journey had been paid on the first occasion; or of £16., if they relied on the evidence that only 10s. had been paid. The jury consulted for about a quarter of an hour, and then gave a verdict for £22.

The case, which occupied more than six hours, did not conclude till nearly seven o'clock. In the award of costs, two guineas were allowed to the plaintiff's solicitor.—*Essex Standard.*

Medical Intelligence.**MEDICAL COMMISSIONER OF THE IRISH CENSUS, 1851.**

HIS Excellency the Lord Lieutenant has been pleased to appoint William Donnelly, Esq., LL.D., the Registrar-General of Marriages in Ireland, to be the Chief Commissioner to superintend the enumeration of the population under the 18th and 14th Victoria, cap. 44. Surgeon Wilde, who was employed to compile the vital statistics in the Census of 1841, and whose able report has become a standard authority on this important branch of the social survey, has been appointed the Assistant Commissioner.

MEDICAL SOCIETY OF LONDON.

At a meeting of the Council of this Society, held October 3rd, G. J. Guthrie, Esq., F.R.S., and G. Owen Rees, Esq., M.D., F.R.S., were elected the Lettsomian Professors for the session 1850-51.

THE CHOLERA AT MALTA.

Oct. 2nd.—The last report of the cholera was favourable, and indicated a very sensible diminution, which has since continued, the attacks yesterday being but four, and no deaths to register.

Selections from Journals.**ON THE MEDICINAL EMPLOYMENT OF ARSENIC IN INTERMITTENT FEVER, AND IN GUTTA SERENA.**

M. MAILLOT, physician to the Military Hospital at Lille, has, in a recent number of the *Gazette Médicale*, recorded the results of his comparative observations on the use of arsenic and sulphate of quinine

in intermittent fever. M. Gibert, physician to the Hospital of St. Louis at Paris, has also communicated several papers to the *Bulletin Général de Thérapie*, on the use of arsenic in diseases of the skin. To these may be added Mr. Hunt's observations on the same subject. We present the following abstract of the above:—

M. Maillot states that from the 11th February to the 18th July of the present year, one hundred and sixty-six cases of ague had come under his care, furnished by one hundred and forty-eight individuals, sixteen of whom had experienced a second attack, and one a third.

The disease was generally simple; few cases presented any visceral complication or signs of miasmatic cachexia. Severe fever, with coma, occurred twice: the cases recovered.

With regard to type, M. Maillot gives the following table:—

Quotidian	48 cases
Tertian	114 "
Double tertian	1 "
Quartan	3 "

With reference to the duration of the disease, the cases were found to arrange themselves as follows:—First attack, 79; first relapse, 48; second relapse, 27; third relapse, 8; fourth relapse, 3; eighth relapse, 1; in all, 166. The relapses yielded generally to one or more doses of sulphate of quinine.

The cases were placed under treatment as follows:—

By expectation, or by an emetic	33
By arsenious acid alone	77
By sulphate of quinine alone	42
By sulphate of quinine and arsenious acid	14

In the majority of cases the treatment was not commenced until after the occurrence of at least one paroxysm in the hospital.

Of the thirty-three cases cured without any medicinal treatment, or by a simple emetic, the duration of the disease was in the following order:—First attack, 18; first relapse, 7; second relapse, 6; third relapse, 1; fourth relapse, 1. Six of these cases were cured by emetics, three had no recurrence of the fit, and the other three had each only one paroxysm subsequently.

The seventy-seven cases treated by arsenic alone presented the following order of duration:—First attack, 40; first relapse, 19; second relapse, 12; third relapse, 5; fourth relapse, 1. This table refutes the opinion that arsenic is useful only in long-standing cases.

The arsenious acid was administered in a solution of one centigramme (= 12½ Eng.

gr.) to thirty grammes (= 7·71 English drachms) of distilled water. In a few exceptional cases the dose was raised to three or four centigrammes. In general not more than two centigrammes (= 0·308 Eng. gr.) were given daily, taken in spoonful doses every hour—a mode of exhibition found to be safer than the administration of the entire dose at one time. The remedy was employed until no recurrence of the fit occurred, and was then continued in the dose of one centigramme daily until the patients were discharged. The average quantity thus taken was nineteen centigrammes (= 2·916 Eng. gr.) In some cases, in which, owing to relapses, it was necessary to increase the daily dose to four centigrammes (= 6·16 Eng. gr.), the whole quantity employed had risen to forty, forty-five, and fifty centigrammes (= 9·16—9·30—7·7—Eng. gr.) All the patients were placed on the most nourishing diet.

Mr. Hunt,* in a paper on the Medicinal Use of Arsenic in Cutaneous Diseases, points out, with regard to the time of administering this remedy, that it should be given with or after a meal, in order that it may enter the general system by the lacteals with the chyle during digestion; because, as remarked by Dr. Golding Bird, if taken on an empty stomach, the medicine will be chiefly absorbed by the venous capillaries, and enter the portal circulation.

Mr. Hunt also observes, with regard to the administration of arsenic, the very important point that it should not be given in increasing doses, as usually directed; because, being a cumulative medicine, its toxic effects are sometimes suddenly and alarmingly manifested. Mr. Hunt, on the contrary, decreases the dose as he observes its influence manifested on the tarsi. The advantage of this plan, Mr. Hunt remarks, is that there is no occasion to suspend its employment, owing to which the disease often reappears and becomes obstinate. Twenty or thirty drops of Fowler's solution is the average dose borne with impunity, according to Mr. Hunt; but he begins with five minims only, until he finds what each individual will bear without injury. "Where the susceptibility is not great," Mr. Hunt states that "a dose of two drachms of the solution can be borne as well in one dose as in twenty;" and that, where the susceptibility is great, the cumulative effects are shown after a few doses.

M. Maillot mentions the following phenomena as observed by him during the exhibition of this medicine.

The circulation did not manifest any change. In some patients the appetite was increased. The urine was not aug-

* Medical Times, Sept. 14, 1850.

mented in quantity. The arsenic could be detected in the urine, but in extremely minute quantities. It was not detected in the saliva or perspiration. The most marked effects were shown in the digestive canal. Under the use of three, or even of two centigrammes, thirst, nausea, bilious vomiting, and diarrhoea, have been observed. These effects have ceased on suspending or decreasing the dose: in some cases, without alteration in the dose, a tolerance of the remedy has been established. One case of gastro-enteritis of several days' duration occurred.

In seventy-seven cases the rate of cure, dating from the first dose, was as follows:—Thirty-eight had no return of the fever; thirty-one had only one paroxysm; seven experienced two; and one, several ague fits. Of the thirty-eight who were cured by the first dose, sixteen were suffering under their first attack. Out of the seventy-seven cases, fifteen relapses occurred.

M. Maillot accurately noted the results of the effects of sulphate of quinine in a comparative series of forty-two cases. Without entering into the details thereof, we may here give the conclusions at which M. Maillot has arrived.

Arsenious acid is a powerful febrifuge, but it is not so certain in its operation as sulphate of quinine; the latter medicine never having failed to effect a cure in his hands. The sulphate of quinine has in several cases been successfully employed where the fever has persisted despite the exhibition of arsenious acid.

The action of arsenic is not so prompt as is that of quinine. With the former the fever recurred in half the cases; with the latter in only one-fourth.

Arsenious acid seems to possess the advantage over quinine, that its use is less frequently followed by relapses, and these at more distant periods.

The injurious effects of arsenic have been unimportant, and have speedily subsided on a suspension or diminution of the dose.

There is no danger in treating intermittent fever with arsenious acid, which is the best substitute for quinine at present known. It is, perhaps, superior, if the quinine be given only in the usual small doses.

M. Gibert concludes, from his observations on the influence of arsenic on diseases of the skin, compared with that of other remedies, that preparations of arsenic do not possess a superior efficacy in these cases; that they are not more dangerous than other medicines (e. g. repeated purgatives), if given with due precautions. That, nevertheless, in many instances which have resisted other means, arsenic has often been given successfully, although M.

Gibert is of opinion that the powers of arsenical preparations have been much exaggerated, and that their use should be restricted to the more obstinate cases. x

ADVANTAGES AND DISADVANTAGES OF CHLOROFORM AS AN ANÆSTHETIC. BY DR. HAYWARD, U.S.

THE only advantages which chloroform possesses over sulphuric ether, Dr. Hayward states, "are that it is more agreeable to inhale than ether, and that a less quantity of it answers the purpose. On the other hand, it cannot be denied that fatal effects have followed its inhalation in several instances, even when administered by the most judicious hands; that in some cases convulsions have been produced, and in others a great disturbance of the brain, causing delirium. In some persons, this affection of the mind has continued for several weeks.

"There are other objections of a minor character. Chloroform is of an acid caustic nature, and if it comes in contact with the skin, unless it be protected by some oily substance, severe excoriation is the consequence. Its administration is generally followed by vomiting and headache, which continues for several hours, attended by a great degree of restlessness and want of sleep. Several cases have come under my care, in which the brain and nervous system have been affected to an alarming extent; though in every instance it was said that a small quantity only of chloroform was administered for the purpose of performing some operation on the teeth.

"An individual in the vicinity was thrown into violent convulsions, which continued for three or four days, during all which time she was in a state of complete insensibility, from the inhalation of the vapour of a few drops of chloroform administered by a careful and judicious physician. It would be easy to multiply examples of this kind; but it is not necessary, for there is a stronger ground on which we can rest our opposition to the use of chloroform, that is, its danger to life. This, it is well known, has already been in several instances destroyed by it. If it can be shown that it has caused the death of a single individual, when properly administered, we cannot fail to have our misgivings of the safety of its exhibition, though it may have been inhaled in almost numberless cases without any ill effect."—*American Journal of the Medical Sciences*, July 1860.

DIABETES MELLITUS IN A CHILD. BY DR. HAUNER, ANSTALT.

C. S. —, one year old. The child was born healthy, and had been brought up

by hand. Without any apparent cause, she began to look ill; to sleep badly; suffer from diarrhoea; and became emaciated. The mother applied to a medical man, who administered calomel and other purgatives, but gave no particular instructions as to the child's diet. The condition of the child continued to get worse, and when seen by Dr. Hauner she was regarded by him as suffering from advanced tabes mesenterica. The treatment at first was simply expectant, consisting of light nourishing diet, and a warm bath every night. The urine, though passed in considerable quantity, was not at this time regarded as being in greater excess than is often seen in children. It was noticed that the child began to crave for liquid food, and would eat incessantly for plain spring water, of which she drank large quantities. The urine dribbled away constantly; the child was restless; her countenance anxious; and her whole aspect sorrowful. The skin was dry, even after the bath. The lower extremities had a constant see-saw movement, which produced excoriation of the genitals. The body wasted away by frequent diarrhoea. The quantity of water drunk daily by this infant was between five and six quarts; sometimes as much as from eight to nine quarts. The urine was voided into a sponge, and its quantity, as nearly as could be ascertained, exceeded that of the water drunk. It was inodorous, pale, rather turbid, slightly coagulable, and sweet to the taste. Chemical analysis detected salts, albumen, and sugar, in abundance. When this was discovered, and the nature of the case was thereby made clear, the treatment was altered. The child was put upon a strictly animal diet of the strongest broths, with eggs. Morphia in small doses was also administered. For some time an apparent amendment was perceived; but in a few weeks the worst symptoms returned, and the child died. The body was greatly emaciated, and the internal organs were for the most part bloodless: the kidneys were the only organs that exhibited actual disease; they were double their ordinary size; their colour grayish white, with dark stripes and spots, and their substance hardened. Numerous small deposits of pus were also seen in their structure, and yellowish fluid could be expressed. The mucous membrane of the ureter and bladder was inflamed.—*Casper's Weekenschrift*.

COURSE OF LECTURES

ON

DISEASES OF THE HEART.

Delivered at St. Vincent's Hospital during the Session 1849-50.

BY O'BRYEN BELLINGHAM, M.D.

Fellow of, and Member of the Court of Examiners of, the Royal College of Surgeons in Ireland, and one of the Medical Officers of the Hospital.

LECTURE XIII.

GENERAL SIGNS OF HEART DISEASE,
(continued).

The pulse as a means of diagnosis in cardiac disease—Morbid conditions of the heart which give rise to varieties of the pulse—Influence of the quality and quantity of the blood—Pulse in hypertrophy, and in dilatation of the left ventricle—Pulse in aortic regurgitation—Cause of the jerking pulse—Intermission, irregularity, and inequality of the pulse—Pulse in contraction of the mitral orifice, and in regurgitation through this orifice—Pulse in contraction of the aortic orifice—Pulse in fatty degeneration of the heart—Summary of the principal varieties of the pulse.

The Pulse as a Means of Diagnosis in Cardiac Disease.

PREVIOUS to, and even for some time subsequent to the discovery of auscultation, the pulse, as an aid to diagnosis in cardiac disease, was of very little value;—indeed, it is obvious that, until the order of succession of the movements of the heart was known, and the auscultatory signs which characterize the several diseased states of the valves were laid down with some precision, any information derived from the characters of the pulse must have been very vague. The obscurity which formerly invested this subject has, however, now been in a great measure dispelled; and the labours of successive investigators have shown that certain forms of cardiac disease are capable of impressing peculiar and well-marked characters upon the pulse.

The pulse is produced by the contraction of the left ventricle, which at each systole propels a certain amount of blood into the aorta; "the blood not being able to escape from the arteries as quickly as it is forced into them by the ventricle, on account of the resistance it experiences in the capillaries, necessarily exerts a pressure on the

elastic coats, and thus gives rise to the pulse." The pulse, therefore, corresponds with the ventricular systole, and with the first sound of the heart; and when the heart, the arterial system, and the blood, are each in the normal condition, the force, the strength, the frequency, and the fullness of the radial pulse, may be taken as a measure of the strength or feebleness of the systole of the left ventricle, of the rapidity with which the movements of the heart are performed, and of the amount of blood transmitted at each systole of the left ventricle.

At each systole of the left ventricle the arterial tubes become elongated: hence, in situations where these vessels have naturally a curve, this curve is increased; and where they are naturally straight, they become slightly curved; when the ventricular systole ceases, they return to their former position. In thin subjects this locomotive movement is perceptible in vessels near the surface, as in the temporal artery, and in the radial at the wrist; and this, which is in reality a natural phenomenon, is not unfrequently set down as a sign of disease. It undoubtedly becomes more marked in cases where regurgitation through the aortic valves or into the aorta itself occurs; but a visible and locomotive pulse in these arteries, unless accompanied by other signs of disease, has no value by itself, and is frequently observed in cases where the heart and arterial system are in a perfectly healthy condition.

At the moment that the pulse is felt, the arteries, in addition to becoming elongated, dilate, and increase in volume. "Every fluid exposed to pressure from behind," Weber* observes, "reacts on the surrounding parts, not merely in the line of direction of that pressure, but on every side; and, therefore, at each contraction of the ventricle, the blood the arteries contain reacts, in consequence of the impulse pressure of the injected blood, not merely longitudinally, but laterally, the arteries being fixed at both extremities." It has been denied by some physiologists that any dilatation of the arteries occurs: it does, however, take place; and M. Poiseuille,† by means of an apparatus capable of being applied round an artery, has determined the amount of this increase to be, for the larger arteries, about the one-eleventh of their diameter. The increased capacity of the arterial tubes depends more, however, upon their elongation than upon their dilatation.

The beat of the pulse in the radial artery is a little later than the ventricular

* Quoted by Dr. Graves in Dublin Journal.

† Magendie's Journal.

systole; but the interval is almost inappreciable, unless the pulse is unusually slow: in arteries further from the centre of the circulation this is somewhat more marked. Thus, according to Weber, the beat of the anterior tibial artery upon the dorsum of the foot is between the sixth and the seventh part of a second later than that of the axillary artery. According to Hamersyk,* the pulse at the wrist, at the temporal artery, and at the femoral, near Poupert's ligament, is perfectly asynchronous; and according to Weber, the pulse of the axillary artery, and of the external maxillary artery, is synchronous.

The radial pulse is said to follow the ventricular systole by a more appreciable interval when the aortic valves permit regurgitation: if it really does so, it is not a sign of any importance. "In debilitated and atonic states of the system the radial pulse," Dr. Williams† observes, "follows the first sound of the heart by a distinct interval, which is occupied by the transmission of the wave along the course of the comparatively lax and yielding artery." "Want of synchronism of the arterial pulse with the heart-beat," Dr. Douglass‡ observes, "has a doubtful connection with valvular disease, and does not occur except in conjunction with more or less dilatation."

In some individuals, to all appearance in perfect health, the pulse is preternaturally slow; in others it is preternaturally quick; and in others, again, it is constantly intermittent. These peculiarities are connected with a similar condition of the heart's action: they appear to be the result of idiosyncrasy, and are sometimes hereditary. The curious fact has been occasionally noticed, that in an individual whose pulse in health intermitted, it became regular on the invasion of illness of a febrile character. It is important to bear in mind that these peculiarities in the pulse are occasionally met with, lest they should be too hastily set down to disease of the heart, with which they may have no connection.

Disease of the right side of the heart exercises no direct influence upon the pulse, but valuable information may sometimes be obtained from its characters in diseased states of the left side of the organ. Although the radial pulse is, in the great majority of cases, an indication of the frequency of the contractions of the left ventricle, it does not necessarily indicate the force of the contraction. Thus, in some cases of disease, although the action of the heart is violent, and its impulse strong, the radial pulse is small and feeble; while, on the other hand, we know that in cases of

local inflammation, the artery going to an inflamed part may beat very strongly, although the heart's action is not at all increased. In all doubtful cases, therefore, it is advisable to place one hand upon the præcordial region, or to auscultate the region of the heart, while the finger is on the radial pulse. "We can thus," Dr. Williams observes, "take a far more accurate survey of the condition of the circulation, than by examining these parts separately; and the utility of this method is by no means confined to affections of the heart."

In several morbid conditions of the heart the pulse becomes quicker than natural: I am not aware of any diseased state of the organ in which it necessarily becomes slower, though this condition of the pulse has been regarded by some as a sign of softening of the muscular tissue of the organ; by others as a sign of a contracted state of the aortic orifice. The pulse, in some diseased states of the heart, becomes stronger, fuller, and harder than natural; in others, softer, weaker, smaller, or feebler than natural; and in others, again, it becomes jerking and receding. In all these cases the pulse may be regular; but it not infrequently happens that its rhythm is disturbed, when the pulse intermits, or becomes unequal or irregular; and these conditions of the pulse may be either combined together or with some of the other states mentioned above.

The morbid conditions under which these varieties of the pulse occur may consist in inflammation of the investing or lining membrane of the heart; in alterations of its muscular tissue; in changes in the capacity of its cavities; in diseased conditions of its valves or orifices; in alterations of the blood; in diseased states of the arteries; and in derangement or disease of other organs reacting upon the heart.

The quality of the blood contained in the vessels exerts a material influence upon the pulse; when this fluid is attenuated, when its red particles are diminished, its serous portion increased, and its viscosity lessened, whether this depends upon profuse hæmorrhage, or arises under other circumstances, the contractions of the heart become more frequent, and the radial pulse is consequently quickened; at the same time, as the strength of the ventricular systole is less than in health, the blood is impelled with less force, and the pulse is weak; while the healthy tension of the arteries being diminished, and their tubes not being filled, the pulse acquires a jerking character, resembling, in a slight degree, the pulse of aortic regurgitation.

The quantity of the blood contained in the vessels, no less than its quality, exercises some influence upon the pulse. "When there is a due correspondence be-

* Gazette Médicale, March, 1844.

† On Diseases of the Heart.

‡ Edinburgh Monthly Journal.

tween the capacity of the vascular system, and the quantity of blood circulating in this system, the coats of the arteries will (Dr. Copland observes*) be kept in that state of healthy tension, or tone, favourable to a regular, firm, free, natural, or healthy pulse, varying chiefly in frequency with the state of the heart's action." When the amount of blood in the system is greater than natural—in other words, in that state of the system denominated plethora—the pulse is full and hard, but not increased in frequency. The sensation produced by an artery in cases of excessive vascular fulness Dr. Copland designates by the term "oppression;" the vessel feeling as if "it were kept in a state of tension, or of distension, in the interval between the beats."

Pulse in hypertrophy of the left ventricle.

—When the parietes of the left ventricle are increased in thickness—in other words, in hypertrophy of the ventricle—its systole will be strong in proportion, the blood will be propelled into the aorta with increased force, and the radial pulse will be strong and hard: its velocity will not, however, be increased; but, as the systole of an hypertrophied ventricle takes a longer time to be completed, the pulse will "dwell longer under the finger." When some dilatation of the cavity of the ventricle is combined with hypertrophy of its walls, the pulse, as long as the circulation continues free, will have the same character, and, in addition, it will be full, because a larger amount of blood will then be impelled at each systole.

Pulse in dilatation of the left ventricle.

—When the cavity of the left ventricle is dilated, and its walls are attenuated, or even though they may preserve their normal thickness, the ventricular systole will be performed with less vigour, and the blood will be propelled with less force, than in a healthy state of the heart: hence the radial pulse will have nearly opposite characters to those of the former state; and, instead of being hard and strong, and dwelling long under the finger, it will be soft and weak, though it may be large.

Pulse in aortic regurgitation.—When the aortic orifice, or its valves, become altered by disease, or when, from any other cause, the valves imperfectly fulfil their functions, the blood will regurgitate into the left ventricle at each diastole, and the pulse in consequence will acquire a peculiar character, being jerking and receding, though regular, while the pulsation of the arteries of the upper extremities and neck is visible and locomotive. This, which is sometimes termed the pulse of unfilled arteries, is very peculiar, and, when once

felt, can scarcely be mistaken. In well-marked examples it appears as if the blood was divided into separate little masses, which pass in rapid succession under the finger. This sensation becomes more marked if we apply the finger to an artery of larger calibre than the radial, as the trachial, and if we lay two or more fingers upon the line of the artery. M. Simonnet has given the name *frôtement globulaire* to this variety of pulse, although he is mistaken respecting its cause. Dr. Hope compares the sensation to that of a hard ball shot with force under the finger, the artery feeling empty; and Dr. Watson,* to the blow of a hammer, without any prolonged swell of the artery, as if successive balls of blood were suddenly shot along under the finger.

Cause of the jerking pulse of aortic regurgitation.—The explanation of the cause of this peculiarity in the pulse is sufficiently simple. We have seen that the arteries,

at the moment that the ventricular systole occurs, dilate; when the diastole occurs, they return to their former state, owing to the elasticity of their coats. We have seen, also, that the arteries, in the healthy state, are always filled: there is a continuous column of blood in them; and the fresh portion, transmitted into the aorta at each contraction of the left ventricle, displaces a column of blood of equal size; an impulse is communicated, and the pulse is felt. Thus when an artery is wounded, or divided across, the blood escapes in a continuous stream, but is accelerated at each ventricular systole, the continuous stream being produced by the elasticity of the artery reacting upon the blood, in the intervals between the systole of the ventricle. Now when the aortic valves imperfectly fulfil their office, the moment that the ventricular systole ceases, a portion of the blood returns from the aorta into the left ventricle, there is a backward motion of the blood in the aorta, as the ventricle dilates, which may be favoured by the elasticity of the coats of the vessel. The arteries of the upper extremities and neck of course feel the effect most: they are less perfectly filled, the healthy state of tension of their coats is diminished, they react with less force upon their contents, and the blood has a forward motion, or, at least, is propelled with any force only during the period that the ventricular systole lasts: hence the column of blood appears to be interrupted, and the pulse has a jerking and receding character.

In cases of anæmia the same effect seems to be produced by the coats of the arteries

* Dict. of Pract. Medicine.

* Lectures on the Practice of Medicine.

losing in some measure their tone or elasticity, in consequence of the deficient nutriment which they receive: the vessels are consequently imperfectly filled, and the blood is moved forward apparently only at the period of the ventricular systole.

This peculiarity of the pulse is not, however, limited to the cases mentioned: it is observed also sometimes in aneurism of the ascending or transverse portion of the arch of the aorta, as well as in cases of disease of the aorta itself, when this vessel has become rigid and inelastic from adventitious deposit, which condition is often accompanied by dilatation of the artery. Here it is produced by the regurgitation of the blood from the large arteries, during the ventricular diastole, into the aorta itself, or into an aneurismal sac.

In addition, in patency of the aortic valves, the pulsation of the arteries, particularly of the superficial arteries of the head, face, and upper extremities, is remarkably visible and locomotive. This was first pointed out by Dr. Corrigan as a sign of patency of the aortic valves; and he observes that it is best seen when the arm is elevated above the head. This phenomenon is most remarkable in the temporal and radial arteries and their branches, in which "the arteries sometimes (as Dr. Williams observes) appear like worms under the skin, wriggling into tortuous lines at each pulse."

Although, in the great majority of cases, the radial pulse indicates exactly the frequency of the contractions of the ventricles, it occasionally happens that every contraction of the left ventricle is not propagated to the radial artery, owing to its systole being too feeble to propel the blood with sufficient force to give an impulse capable of being felt with the finger. If this recurs with regularity at every second beat, the pulse will appear to be preternaturally slow; and this, no doubt, was the condition in some of the cases of remarkably slow pulse reported previous to the discovery of auscultation. The error will be corrected by laying the stethoscope upon the precordial region, while the finger is upon the pulse. When this occurs at longer and irregular intervals, intermission of the pulse is said to occur; which we have next to consider.

Intermission and Irregularity of the Pulse.

The rhythm of the motions of the heart, and the irregularity of the contraction of the ventricles, are in general manifested by the pulse at the wrist: the heart's action cannot be intermittent or irregular without its being communicated to the radial artery: but the pulse may intermit, although the heart contracts regularly, if

every fifth, sixth, or seventh ventricular systole, as the case may be, is too feeble to propel a sufficient quantity of blood to communicate an impulse to the radial artery.

Intermission may be regarded as the slightest degree of derangement of the heart's action. It is not uncommon, as has already been observed, in individuals in whom the heart and arterial system are perfectly healthy: the intermissions may occur at regular or irregular intervals, and this state may continue through life. This form of derangement of the rhythm of the heart's motions is not uncommon in persons advanced in life, in gouty subjects, and in individuals labouring under derangement of the digestive organs, accompanied by flatulence. It is frequently likewise met with in cases of disease of the valves, or of the muscular tissue of the heart, when it is often accompanied by irregularity, or inequality of the pulse, and it becomes then a sign of considerable importance.

By an *unequal* pulse we understand one in which some pulsations are strong, and others weak. By an *irregular* pulse, one in which a few rapid beats are succeeded by one or more slower beats, and when the interval between them is different. Inequality and irregularity of the pulse are much more unfavourable signs than simple intermission, and are not observed except in cases of disease. Both are frequently met with in the same cases, and both accompany certain diseased states of the valves at the left side of the heart, of the muscular tissue of the organ, and of its investing membrane, the pericardium.

Pulse in contraction of the left auriculo-ventricular orifice.—When the mitral valve or the left auriculo-ventricular orifice become diseased, so as to obstruct the passage of the blood from the left auricle into the left ventricle, the radial pulse will necessarily be weaker than natural, and will occasionally intermit. When this condition of the valve or orifice is more advanced, and the obstruction to the passage of the blood through the orifice becomes greater, the pulse, in addition to being weak and intermittent, will become small, irregular, and unequal, although the heart's action is strong. Mr. Adams,* of this city, was the first to call particular attention to the want of correspondence between the strength of the pulse at the wrist and the impulse of the heart in this form of disease: "the heart often beats so violently (he observes) as to shake the patient in his bed, while the pulse is small, weak, and irregular." "I know not how," he adds, "to describe

* Dublin Hospital Reports.

it otherwise than by saying that it appears as if there were two pulses; one slow and deliberate for two or three beats, succeeded by three or four rapid and indistinct pulsations."

Pulse in mitral regurgitation.—When the mitral valve imperfectly closes the left auriculo-ventricular orifice, and regurgitation into the auricle occurs at each ventricular systole, the pulse will be scarcely affected if the aperture is very trifling; when larger, the pulse will become weak and small, and will intermit, particularly when the circulation is hurried. When the mitral orifice is much enlarged, and permits a considerable portion of the blood to regurgitate into the auricle at each ventricular systole, the pulse, in addition to being small and weak, will become irregular and unequal, and will almost exactly resemble the pulse of considerable contraction of the mitral orifice.

Hence, in the advanced stage of these two opposite conditions of the mitral valve and orifice, the pulse presents similar characters: thus, when this orifice is considerably diminished in size, a smaller quantity of blood can enter the ventricle from the auricle at each diastole; the ventricle, therefore, is imperfectly filled, and less blood than natural is transmitted into the aorta at each systole; the pulse necessarily becomes small and feeble, and eventually intermittent, irregular, and unequal. Again, when the mitral orifice is preternaturally dilated, a considerable portion of the blood is transmitted backwards into the auricle at each systole of the ventricle, and the same result follows; a smaller quantity than natural is transmitted into the aorta at each systole, and the pulse likewise becomes weak, small, irregular, and unequal in proportion.

Pulse in contraction of the aortic orifice.—When the aortic orifice is slightly contracted the stream of blood transmitted into the aorta at each systole of the left ventricle must be somewhat less than natural; but as the walls of the ventricle under such circumstances almost always become hypertrophied, what is wanting in quantity is made up by the strength of the ventricular systole, and the pulse will be neither weaker nor smaller than natural, and will be perfectly regular. When the contraction, however, becomes extreme, as sometimes happens, though much less frequently than at the mitral orifice, the pulse will then become small and intermittent, irregular and unequal, resembling the pulse of considerable contraction of the mitral orifice, or of free regurgitation through it.

Pulse in softening of the heart.—A small, weak, irregular, and unequal pulse is not, however, peculiar to cases of valvular dis-

ease: the radial pulse has the same characters, and in a still more marked degree, in the advanced stage of softening of the heart from fatty degeneration or other cause, particularly when combined with dilatation of the cavity of the left ventricle. The contractile power of the ventricle being necessarily weakened when the muscular tissue is softened, the force with which the blood is propelled into the aorta will be diminished; while the weakened ventricle, being unable to empty itself at each systole, the quantity of blood which it propels into the aorta is less than natural: hence not only is a smaller quantity of blood transmitted into the aorta, but it is transmitted with diminished force, and the pulse under such circumstances becomes sometimes so small, weak, irregular, and unequal, that it is impossible to count it.

A small, weak, and irregular pulse is also observed in cases of pericarditis accompanied by copious liquid effusion, by which the heart's movements are materially impeded; or where fibrinous concretions form in the cavities of the heart previous to death, by which the passage of the blood through them is obstructed; or in any case where much embarrassment of the cardiac or pulmonary circulation exists, as towards the close of several diseases of the heart or lungs.

Summary of the Principal Varieties of the Pulse.

In the following summary of the more prominent characters of the pulse in the several diseased states we have been considering, the varieties of the pulse are arranged according to their regularity or irregularity. The first division includes the cases in which the pulse is usually regular; the second, those in which the pulse is usually irregular.

Pulse Regular.

1. In plethora the pulse is full, hard, and resistant, but not more frequent than natural.
2. In anæmia the pulse is smaller, weaker, and quicker than natural, and in addition has a jerking character.
3. In hypertrophy of the left ventricle the pulse is "strong and prolonged," but not quicker than natural. When dilatation is combined with the hypertrophy the pulse is in addition full.
4. In dilatation of the left ventricle without hypertrophy the pulse is large, but weak.
5. In dilatation with attenuation of the left ventricle the pulse is weak and soft, easily quickened, and occasionally intermittent.
6. In patency of the aortic valves the

pulse is jerking, visible, and locomotive, but its frequency is not increased.

7. In diseased states of the coats of the arch of the aorta, with increase of the calibre of the vessel, the pulse has the same characters, but in a less marked degree.

8. In aneurism of the arch of the aorta the pulse may have a different strength in each wrist, or it may be absent altogether in the radial artery on one side. It may also have a jerking character, resembling that of aortic regurgitation.

Pulse Irregular.

1. In extreme contraction of the mitral orifice the pulse is small, weak, intermittent, irregular, and unequal.

2. In cases of regurgitation through the mitral orifice, when slight, the pulse is little altered; when extreme, the pulse has the same characters as in considerable contraction of the orifice.

3. In contraction of the aortic orifice the pulse presents no peculiarity unless the degree of contraction is extreme, when it becomes small, irregular, and intermittent.

4. In fatty degeneration of the muscular tissue of the left ventricle, the pulse, in the advanced stages, is small, weak, irregular, and unequal.

5. In pericarditis with copious liquid effusion the pulse presents somewhat the same characters.

6. In cases where fibrinous concretions form in the cavities of the heart the pulse suddenly becomes small, weak, intermittent, and irregular.

From what has been said, it may be gathered, that in several forms of cardiac disease the characters presented by the pulse are of a nature materially to aid the diagnosis: and if the different cardiac lesions were met with always distinct from each other, and uncomplicated with other affections, the signs derived from the pulse would be most valuable. Unfortunately, however, this is not often the case. Two or more forms of structural disease are frequently combined; for instance, hypertrophy and dilatation of the left ventricle are very frequently associated; and, as these morbid conditions are a frequent result of disease of the valves or orifices, we may have obstructive or regurgitant disease of the aortic or mitral valves, or of both, combined with hypertrophy, or dilatation of the left ventricle, or with the two latter states. In addition, disease of any part of the heart may be associated with a state of anæmia or hysteria, with functional derangement, or a nervous habit, or with some of the other morbid conditions that have been alluded to; when the pulse, if

trusted to alone, would be more likely to lead into error than to assist the diagnosis.

It must be borne in mind, too, that intermission and irregularity of the pulse may ensue in any diseased state of the heart, when the pulmonary circulation becomes greatly obstructed. It should also be recollected that a very trifling morbid alteration of the valves at the left side of the heart, which may be accompanied by a loud *bruit de soufflet*, often causes no alteration of the pulse; while in a very advanced stage of the same disease, when the pulse becomes intermittent and irregular, an abnormal sound may be absent. Finally, as the systole of the right ventricle exercises no direct influence upon the pulse, the walls of the right side of the heart may be hypertrophied, or their cavities dilated; or its valves or orifices may be diseased, without the pulse indicating in the slightest degree morbid alteration.

Original Communications.

BRIEF REMARKS UPON

THE CHOLERA AS IT APPEARED AT CARDIFFE AND DOWLAIS IN THE SUMMER OF 1849.

By G. E. WEBSTER, Esq.

(Read before the *Abernethian Society*,
December 6th, 1849).

HAVING been resident for some considerable time last summer at Cardiff and Dowlais during the visitation of cholera, it is my intention to record a few of the various incidents which struck me as worthy of remark, and to notice any causes which may seem to have accelerated, retarded, or obstructed the progress of this malady in those places.

Epidemics of all kinds are very frequent in the town of Cardiff. It is an over-populated, densely-crowded seaport, having considerably increased in commerce and population within the last few years, without due attention being paid, either by public enterprise or private speculation, to the domestic comforts, necessities, and conveniences of the humbler classes. The site of the town, from lying almost on a dead level, afforded no facilities for drainage; consequently overflowing cesspools and stopped-up drains were of too frequent occurrence. In addition to these evils the Glamorganshire canal, which runs

through the centre of the town, acting as a convenient receptacle for all sorts of filth, was entirely drained of its water for some distance, owing to repairs being requisite, leaving the refuse matter exposed to the scorching rays of the sun.

In this locality, and the small streets composed of lodging-houses filled with Irish to an extent almost incredible, the disease committed the greatest ravages.

The interference of sanitary measures was not less needed at Dowlais than at Cardiff, though, the former having the advantage of being situated on the side of a hill, the natural drainage was good.

The people, generally speaking, were in a better condition of life, their wages good, and work constant; their habitations, however, and conveniences equally bad. In conjunction with these the severe and exhausting nature of their employment, and the consequent incitement to drink, must be considered among the predisposing causes of disease.

The experienced eye might frequently detect in the patient's appearance and expression of countenance indications of the forthcoming evil. My attention was drawn to this point by Dr. Sutherland, a commissioner of the Board of Health, in order to induce persons to leave those localities where cholera had made its appearance, and my own subsequent observation fully bore out the truth of this assertion.

Purposely passing over a minute detail of the symptoms of cholera, I may remark that the cramps and vomiting usually commenced and recurred together; but what relation they bore to each other in the shape of cause and effect I cannot tell. It was remarkable, in almost all those cases which recovered from the stage of collapse, how well the mechanism of life was depicted, and what functions are most necessary for supporting and prolonging human existence, an alteration taking place in those functions first, and secondly, in those which cannot be considered essential to life. Thus nature, gradually reviving, begins to develop a degree of animal heat; the pulse, returning at intervals, ultimately becomes quick and hard, the respiration is somewhat easier, the features and hands become less blue, the vomiting and purging gradually cease; the excretions being changed in appearance often assume a greenish or dark cast, and,

finally, the secretion of urine, before so totally suppressed, is restored.

I found there was no difference in the time of day in which persons were attacked, as they were taken ill at all hours throughout the twenty-four, but generally after returning from work. This may be attributed to the fact that their employment lasts incessantly throughout the day and night, different relays of men going on every eight hours. At Cardiff, on the other hand, the hours of seizure were most frequent between sunset and sunrise.

The days of the week also had their respective increase in mortality and number of attacks: I found that the early part of the week almost invariably had the heaviest mortality. This was attributed in great measure to the wages being paid on the Saturday, and the idle day Sunday intervening, a greater part of them was expended in the beer-shop during that period. By way of experiment, through the instrumentality of the manager of the works, all the beer-shops were closed from six o'clock in the evening, and to remain so during Sunday. The rate of mortality certainly was diminished on the two subsequent days, but increased to the usual amount on the Wednesday and Thursday.

These measures, with some others which were adopted, for restraining persons from the abuse of stimulants, were, I think, calculated to do, and I have no doubt did, some harm; for whilst, on the one hand, as it was seen, they did not restrain the habitual drunkard, on the other they frightened numbers of individuals into a different mode of living, so that they abjured *in toto* their accustomed amount of stimulus, which from long habit had become almost necessary to their existence. Nor can I advert too strongly to the folly of persons, even in the higher classes of society, totally abstaining from articles of diet to which they have long been accustomed, simply because statements have gone forth from individuals no wiser than themselves that such articles have a choleraic tendency. All sudden changes, I believe, have a very injurious tendency, and may be fairly ranked among the predisposing causes of cholera.

The migratory nature of, and the mode in which this malady travelled was very remarkable—that it should

pursue the same course, visit the same localities, break out in exactly the same houses in these localities, rage with violence in the circumference of an isolated spot, leaving that spot scatheless, free, and untouched, overlook towns, and not only towns, but a whole county, leave one part of a town and break out in the opposite direction, and then becoming mitigated, subsequently return to the scene of its former visit.

Instances of all these have come under my notice. It was foretold, long before its appearance at Tooting, from its course in foreign countries, that England would again be visited, and the result verified the prediction. Exactly the same locality and house in Dowlais was first visited as in 1832. The town of Tiverton, in Devonshire, escaped entirely, as it formerly did, being surrounded by numerous towns on the south-west coast in which it was raging. No record appears of a single case in the whole county of Hereford; and, finally, having committed great ravages on the south-west portion of Dowlais, it gradually travelled up to the north-east point, where the mortality became very great; but in a single night the wind veered round to that quarter, the disease became mitigated, and broke out again in its former locality.

Upon the first outbreak of the epidemic at Cardiff the usual premonitory symptoms were very much neglected, medical assistance frequently not being obtained until the more decided characteristic symptoms had set in, and sometimes even the stage of collapse come on.

Persons, however, soon became so panic-stricken, that every headache and pain was construed into an approaching attack of cholera; and I have no doubt that fear alone in some instances was the sole cause of an attack, of which the following is a powerfully striking instance, and where collapse came on suddenly; it occurred to a woman whose husband was labouring under consecutive fever:—The medical man having left the house but a very few minutes, and seeing some more patients in the same street, was suddenly sent for back again to the identical house, on account of the woman being struck. She was in the stage of collapse, cold, and pulseless, her vomitings and evacuations being very characteristic. It was ascertained upon inquiry that a neighbour had dropped in to ask after the

health of the man; the wife told her that he had hiccough, to which she officiously replied, "that it was all over with him if it came to hiccough." From that moment the wife was seized, and died in four hours, no treatment appearing to rally her in the least.

Upon the advice of Dr. Sutherland the system of house visitation was adopted and rigorously carried out. Certain districts were allotted to lay individuals, whose business it was to visit every house in the district twice in the day, and inquire concerning the health of every occupant. Any symptoms of illness being manifest, I was immediately sent for to the patient, and by me subsequently transferred to the respective medical officer of that district. By this means persons were seen from the very first, their fears and apprehensions frequently dispelled, and a most searching investigation into the sanitary condition of their domiciles was made.

The general routine of treatment adopted was, in the first instance, calomel and opium every hour, with brandy, counter-irritants, the application of warmth, and the administration of salines. The opium and brandy were, however, soon abandoned, for this reason—it was found that those who had passed through the acute stage generally had a severe attack of consecutive fever, and most of these died comatose; and it was often difficult to tell how much of the evil was to be attributed to the opium, and how much to the decreased action of the kidneys. Again, opium, when administered in small and repeated doses, takes on the nature of a stimulant; and it was found that stimulants of all kinds did harm; very often they had little or no effect upon the system, and when any effect was produced, the subsequent amount of depression was greater than that prior to the exhibition of the stimulant.

Counter-irritants I found of service in three ways, but not until the disease had become somewhat mitigated, and there was hope of ultimate recovery. Frequently, when the collapsed stage had passed off, and the evacuations were diminished in quantity and altered in quality, vomiting would still continue, and resist all endeavours to allay it. The stomach would seem to have contracted a morbid habit of expelling its contents the wrong way: in these cases the application of a smart

blister over the region of the stomach would produce the desired effect. Again, not unfrequently an intense burning pain would be complained of at the pit of the stomach, even if vomiting had ceased; in these instances also they were useful. And thirdly, they were advantageous in consecutive fever when there was a tendency to coma.

The routine of treatment adopted at Dowlais was very similar, still adhering to calomel, which was administered pretty freely in doses from one to five grains every quarter of an hour without opium, the simple effervescing saline being given in conjunction with it. In some instances this treatment acted as a charm in checking the profluvial discharges, whilst in numerous others it had not the slightest effect. Carbon, in the form of burnt cork, was occasionally substituted for the saline, and produced good as well as bad results; but I think, on the whole, it was more beneficial to children and young persons than grown-up people. In not a few instances even of active cholera, but especially of insidious diarrhoea, the following prescription of Mr. Girdlestone's—viz., Dover's powder, carbonate of soda, and sulphate of copper, in very small doses,—produced a marked effect when other astringents had failed.

The indiscriminate administration of chalk mixtures I think very frequently did harm in the premonitory diarrhoea; for if any good was to be the result, it generally became manifest after the first two doses; but if not, and still persisted in, it only irritated an already too highly irritable mucous membrane. Induced partly by the modest manner in which two proposed remedies were promulgated, and partly because the result could not be much worse than with other means, I put them to the test of practical experience;—these were olive oil and colchicum. I administered an ounce of olive oil to six patients every quarter of an hour with three grains of calomel for four doses, and afterwards ordered them to drink copiously of lukewarm water until either the evacuations lessened or became altered in appearance. The result was that five of them died; the sixth was put upon the saline treatment, and ultimately recovered. With the colchicum I had no better success, for in four cases they all died. During an acute attack of cholera, as to what the patient might eat or drink, my

directions were very concise,—“Let him eat what he likes, and drink what he likes,”—for I felt perfectly sure that solids were quite out of the question, the general demand being for cold water; and I do not believe that the imbibition of fluids in any way aggravates the purging, as stated by some persons, but, on the contrary, proves an useful auxiliary to that incessant dry retching, than which nothing is more distressing, fatiguing, and exhausting to the patient.

Finally, I think that altogether, during an acute attack, too much reliance is placed upon medicine, and too little attention paid to sustaining the system, which has to undergo such a severe ordeal: and I would strongly advocate the administration of nutritious substances from the very first, either by the mouth or by injection, at least three or four times a day; for though it be a mooted question whether absorption goes on or not, harm cannot possibly be done; and it may be a means of diminishing our awful lists of mortality, should a fresh outbreak occur this spring, or return again at the expiration of another sexdecennial period.

With regard to the cause of cholera, that is, I may say, entirely obscure, but perhaps not more so than of other epidemics. We cannot tell why at one time, small-pox; at a second, continued fever; at a third, influenza; and at a fourth, cholera should prevail: but we can tell in what regions and localities these epidemics, when prevailing, commit the greatest havoc. The epidemical nature of cholera is a most important topic for consideration and discussion in two aspects,—the first, as to the nature of epidemic force as a cause in *inducing disease*; in other words, *epidemic force per se*; and secondly, with reference to those causes and circumstances which assist in adding to its power, and giving it a greater tendency and facility to spread.

Supposing (to use an arbitrary explanation in numbers) that the sum of cause or causes required to produce the given effect is five, then, if the *epidemic force* were equal to five, it would attack any one with whom it came in contact; but supposing it were equal to three only, it would not affect a healthy individual: but if the additional two were made out by intemperance, fear, anxiety, bad air, or other cause or causes, the effect would be the same as if the neces-

gery number were made up of epidemic force alone.

The epidemic character of certain diseases is not only a remarkable, but a most important, circumstance. Their influences appear to visit, and impart certain properties to unhealthy places in which diseases are ordinarily found, or even healthy places to which no diseases are peculiarly attached, and also act upon causes which usually produce certain illnesses, so that these illnesses shall be changed or converted, and invested with the type, nature, and power of the prevailing epidemic. Thus, during the whole time I was at Dowlais, I do not remember attending a single case of any other illness but cholera, except accidents, which, from the vast number of men, and the nature of their employment, were extremely common; nevertheless, even *these* were considerably below the average, and the ratio per week very much diminished. Cholera will sometimes suddenly appear in apparently healthy places where no disease before existed, and where none could be well expected to appear; but it will more certainly invade unhealthy localities, or impure dwellings, ill ventilated houses, the neighbourhood of foul drains, open cesspools, &c., formerly the abodes of typhus and other fevers, and ravage such places to the exclusion of fevers before prevalent. It will, again, select for its victims the weakly, the fear-stricken, and the intemperate; but even the healthy and temperate will not be invariably exempt from its attacks. Its abode is uncertain, and its stoops or pounces are often sudden and capricious: its type and fatal character also are very varying, inconstant, and ever changing. We frequently find cholera in a place affected to be one week deadly in its effects, and utterly bidding defiance to remedies; in the next, it may be more benign, and readily controllable by curative agents.

Many other diseases have similar attributes; and against these, in the same manner as against cholera, full health furnishes no certain security; yet the prone or predisposed are for the most part the victims. Healthful localities, again, do not possess entire immunity; for they are occasionally the seats of the ravages of disease; yet places of a contrary nature are the chief scenes of its presence and its power, and supply the greater number of fatal cases.

The abodes of plenty are not safe, but the dwellings of want, woe, and wretchedness, are far less so.

OBSERVATIONS

ON THE

NATURE AND CHEMICAL CHARACTERS OF THE "DUMB-BELL" CRYSTALS DESCRIBED AS OXALATE OF LIME.

By DR. GOLDING BIRD, F.R.S.

MORE than eight years have elapsed since, among other forms of crystalline deposits in the urine described by me, I especially drew attention to the frequent occurrence of oxalate of lime in octahedral crystals. These observations (although they appear, from the tone in which they were alluded to by other writers at the time, to have been received with some hesitation) have since been amply confirmed by almost every one who has taken the trouble to examine the urine in health and disease with any amount of care. Perhaps too much importance can hardly be attached to the examination of the urine in many forms of disease with a view to the detection of the oxalate of lime, on account of the very serious phases of disease it often indicates, and of the important therapeutical hints it affords.

It is, however, with relation to one peculiar form of crystalline deposit, which I described as a variety of oxalate of lime, that I am anxious very briefly to direct the attention of your readers: I allude to the very remarkable crystals I observed about nine years ago, and first figured in a paper published in Guy's Hospital Reports (vol. vii. for 1842): these crystals, which, from their remarkable shape, I called *dumb-bells*, obey under the microscope the action of the same solvents as the octahedral crystals of oxalate of lime, and as, moreover, they always alternated with these, and were often found with them, I regarded them as *zeolitic* crystals of oxalate, under the idea that they were made up of a number of acute octahedra arranged in a radiating manner. I confess, however, that I was never quite satisfied with this view of their nature in consequence of their optical characters differing so completely from

those of the octahedral oxalate. The latter salt, in obedience to the well-known law of cubic and octahedral crystals, not possessing the power of doubly refracting a ray of light, did not affect plane polarised light. But the dumb-bells, on the contrary, possess an energetic doubly-refracting power, and powerfully depolarise the light transmitted through the Nicol's prism of the polarising microscope. The rays thus transmitted, when analysed by a plate of tourmaline, or a single image prism, exhibit a very beautiful image, the dumb-bells presenting a series of concentric coloured rings, traversed by the well-known black cross. These facts have induced me to take every opportunity in my power of carefully examining the crystals in question; and very lately, having a patient under my care whose urine deposited a large quantity of dumb-bells unmixed with any other crystal, I was able to submit them to examination with the following results:—

A. Observed during a fortnight these dumb-bell crystals never occurred for two days in succession, either disappearing completely, or existing in mere traces, always alternating with octahedral crystals, and ultimately quite disappearing.

B. Kept under water for ten days in a greenhouse, in July, the temperature seldom being below 85 or 90° in the day-time, they underwent some change; the water became turbid, and evolved a foetid ammoniacal odour. Under the microscope some of the dumb-bells had disappeared, and large octahedral crystals of oxalate of lime, which did not exist previously, were now visible.

C. The dumb-bells dissolved slowly in boiling dilute hydrochloric acid; and from this solution ammonia threw down an amorphous white precipitate. The whole was left to evaporate spontaneously in a watch-glass; large and beautiful cubes of hydrochlorate of ammonia, unmixed with any of the usual plumose crystals of that salt, were left.

D. Ignited in a platinum spoon, these dumb-bells became black, evolved an odour of burnt horn, and at a moderate red heat became quite white. Examined under the microscope, the form of the crystals was in no way affected. The dumb-bells had simply lost their transparency, and had become quite opaque. It was, however, evident that

they had undergone a most important chemical change; for they now restored the colour of moistened red litmus paper, and dissolved in acetic acid (in which they were, before ignition, quite insoluble) with active effervescence. In water they were quite insoluble.

E. The ignited dumb-bells (D) dissolved with active effervescence in dilute sulphuric acid, and the solution left by evaporation crystals of sulphate of lime.

F. Some of the dumb-bells recently collected from the urine and washed, were boiled in strong nitric acid; they dissolved without any evolution of gas, and formed a clear white solution. A drop of this, spontaneously evaporated on a plate of glass, left a beautiful mass of dumb-bells, rather larger and more perfect in outline than they were before solution. Hence it is evident that boiling nitric acid simply dissolves, but does not change, the crystals.

F. Boiled in hydrochloric acid, the fresh dumb-bells dissolved, and, by spontaneous evaporation, left beautiful tufts of long radiating acicular crystals, insoluble in water, but soluble in dilute hydrochloric acid.

These experiments are sufficient to invest the dumb-bell crystals with great chemical interest; and I can only regret the few opportunities we possess of collecting them in sufficient quantities for more minute investigation. We may, however, safely draw some conclusions from the above investigation, superficial as it is.

That these crystals are a salt of lime, capable of being converted into a carbonate by ignition, is proved by experiments D and E. That the acid combined with the lime cannot be the uric or sulphuric, is obvious from the remarkable circumstance of their dissolving in boiling nitric acid without change (exp. F). The peculiar change presented by these crystals by keeping in a warm place under water (exp. B) indicates their undergoing a putrefactive change with the evolution of ammonia; hence it may be inferred that the acid combined with the lime contains nitrogen. The cubic form of the crystals of hydrochlorate of ammonia in exp. C is that assumed by this salt in the presence of urea.

Every one at all familiar with the microscope is well acquainted with the

crystals of oxalurate of ammonia and their action on polarised light: this salt presents so close a resemblance in its radiated structure, in its doubly-refracting power, in the arrangement of its rings and cross in polarised light, to the dumb-bell found in urine, that I think we have much presumptive evidence (for I dare not say more) in favour of their being an oxalurate of lime instead of an oxalate, as I had declared it to be. It is true that the properties of the crystals above described are not to be regarded as conclusive; but the evolution of ammonia during the putrefactive fermentation (exp. B), the crystalline form of the hydrochlorate of ammonia (exp. C), indicates the probable presence of urea. Now, although oxaluric acid does not contain urea ready formed, yet it contains its elements, and oxalate of lime differs from oxalurate of lime only in their absence, and in containing the constituents of water; for

	C	N	H	O
2 atom oxalic acid . . .	4			6
1 „ urea	2	2	4	2
	6	2	4	8
-1 „ water			1	1
= „ oxaluric acid	6	2	3	7

Nothing is more likely than the combination in the blood of the *nascent* elements of oxalic acid and urea. And in connection with this, it must not be forgotten, that dumb-bell crystals, exactly like those I observed in urine, have been detected by Dr. Garrod in the blood. Admitting this, we at once see the simple relation of the dumb bells to the octohedra; of oxalurate, to oxalate of lime,—their alternation, mixture, and mutual replacement in urinous deposits all become clearer.

In venturing to regard the dumb-bell crystals as those of oxalurate of lime, I cannot help here alluding to the opinion expressed to me by Baron Liebig some years ago, that he had no doubt the oxalurate of lime would be one day detected as a constituent of urinary deposits.

Dr. Hassall,* so favourably known

* May I be permitted to express an anxious hope that the work projected by this gentleman on Human Crystallography will, notwithstanding the delay of its publication, be placed before the profession. I have been favoured with an opportunity of inspecting very many of Dr. Hassall's drawings for this work, especially of those

as a microscopical observer, has informed me that he has met with crystals exactly like the dumb-bells I have described, in the residue left by the spontaneous evaporation of a drop of urine on a plate of glass, but differing from them in their being soluble in water. I am not aware whether he has made any researches into their chemical properties.

I must beg to apologise for the length of this paper, which I should not have ventured to have inflicted upon the readers of your valuable journal, as I fully intended deferring any allusion to these observations until the publication of the third edition of my book (*Urinary Deposits*), now in the press, had not my attention been drawn to a paper by Dr. Frick, of Baltimore. In this communication—which, from its republication in that excellent and admirably conducted periodical, the *Edinburgh Medical and Surgical Journal* for this month, will obtain a large circulation,—the author has declared the dumb-bell crystals to consist of uric acid. Such an opinion requires no serious refutation, as crystals which can be ignited without losing their form, but are converted into carbonate of lime, and which can dissolve in boiling nitric acid without change, cannot, even by those most ignorant of chemistry, be regarded as consisting of uric acid. It is difficult to understand how so careful an observer as Dr. Frick could have committed such an error. I should not have thus alluded to this statement, had not it involved a most important indication of treatment, for it is obvious that if the crystals in question consisted of uric acid, their therapeutical indications would be very different from that which I have assumed them to be.

48, Russell Square, Oct. 16th, 1850.

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 18th inst. :—Messrs. C. Brettingham—T. B. Washbourn—R. G. Horton—M. W. Flewitt—C. Gordon—T. Lowe—C. Booth—T. A. Haigh.

made from preparations I had great pleasure in placing at his disposal. Their accuracy and beauty are unequalled; and a work of this kind will prove of the greatest value to those who employ histological observations for the elucidation of disease.

NOTES
ON THE STRUCTURE, &c., OF THE
TEETH.

BY C. SPENCE BATE, ESQ.,

[Continued from p. 333.]

Enamel.

1. In mammalia, both in relation to the development of the whole structure of the tooth, as well also in its respective importance in fulfilment of certain required conditions, the enamel succeeds the dentine. For scarcely has a scale of the latter been deposited upon the apex of the pulp from which it is developed, than lines of enamel are deposited upon its external surface.

2. The tissues of the pulp from which the enamel is developed are of a description similar to those which exist in the dentinal pulp; but they are present under peculiar modifications, not only in comparison with the pulp which develops the dentine, but also as regards the character of enamel in different classes of animals.

In *man* and *carnivorous animals*, in all of which the enamel covers the crown of the tooth, the enamel-pulp consists of nucleated cells larger in size generally than those which exist in the dentinal pulp of the same tooth; also areolar tissue, which has the peculiarity of nucleated centres exhibited, which gives to the structure a reticulated appearance, a circumstance which renders to this tissue a character peculiarly its own (Fig. 9), the whole is em-

FIG. 9.

Areolar tissue from enamel pulp of kitten at birth.

bedded in an unctuous fluid plasma, and yellowish transparent, confined by an external membrane. The organ in this character of tooth is wholly ex-

travascular, at least during the period of the development of the enamel, and is supplied with calcareous material from bloodvessels which ramify upon the capsule which invests the whole tooth, which I presume passes through the outer wall of the enamel pulp by endosmosis.

Among the *rudimentary* tribe of mammals the enamel is developed from a pulp which dips into clefts or fissures existing between processes formed by the dentinal pulp, and in this class of tooth, to unassisted vision, the pulp from which the enamel is developed cannot be distinguished from that which develops the dentine; but when the test of the microscope is applied, certain conditions may be observed in the enamel pulp which cannot be seen in the organ whose attribute is to develop the tooth substance; these conditions are, that the ultimate secreting cells of the enamel pulp are not interspersed with bloodvessels; that whereas in the dentinal pulp bloodvessels extend into the newly deposited material, in the enamel a layer of cells, the true extra-vascular enamel pulp, separates the vascular portion of the pulp from immediate contact with the enamel (fig. 10); these cells are transparent,

FIG. 10.

Transition cells from enamel pulp of lamb at birth, as they exist between the vascular portion of the pulp and deposited enamel.

and seem to correspond with the organ which develops enamel in carnivorous

teeth, and hold a relation to the diameter or thickness of the enamel which it develops; the rest of the pulp goes to form the crusta petrosa or cementum of the tooth, under which head it will be again alluded to.

The cells which float in the liquid plasma obtain a uniformity of character as they approach towards the completion of their development (fig. 11), which

Fig. 11.

Transition cells from enamel pulp of kitten at birth.

is carried out in a manner nearly corresponding with that exhibited in the development of the intertubular structure of dentine.

3. The attachment of the enamel to the dentine is chiefly mechanical; and the mechanism is so constructed as to yield the most enduring strength, both in the arrangement of the enamel cells upon the surface of dentine, and the conformation of that surface;* for although, as before stated, the process of its development resembles that of intertubular dentine, yet it is not like it deposited in layers or scales succeeding one another, each directly united to the last, but the earliest deposition of enamel upon the already developed dentine takes place in lines, which trace a series of corresponding curves in a more or less waving character upon its surface in a manner, as far as I have been able to make out, peculiar to genera.

Thus in man the curves are formed more abruptly than in any other animal that I have examined (fig. 12); while in the donkey they traverse in a line more straight, in a direction from the apex to the base of the tooth, sometimes one line uniting itself to the next. In the calf the lines are direct in their course from one extremity of the tooth to the other, and run very equidistant and

* Additional strength the connection probably receives from the ossification of the intermediate membrane, which is common to the two pulps: this idea is strengthened by the occasional passing of the dentinal tubes into the enamel. This fact is pointed out by Mr. Tomes in a paper lately read before the Royal Society, and published in the *MEDICAL GAZETTE*, to exist in the hare; but I have also seen the same phenomenon in the teeth of the ass, sheep, and monkey.

Fig. 12.

Enamel as seen first deposited on the surface of dentine; from child at birth.

parallel. Although it may be described as being deposited in lines, yet these lines are not continuous—at least, in the early part of the process; but spots are deposited, at tolerably regular intervals, in the same line, which spots become the centres of enamel growth, and continue to increase longitudinally until they form one continuous line: they also increase in their diameter, but not relatively to the length. The intermediate spaces are filled up by fresh deposit brought forward from the original centre of ossification of the enamel, in a manner repeating that which has been attempted to be described.

How far the intermediate lines which fill up the spaces between the original ones may correspond with each other, or differ in the latter deposition, I cannot say, but I believe that it is due to this cause that each row of basaltic prisms of enamel directs their curvatures in opposite ways—that is, the convex bend of one row overlies the concave of the next (fig. 13), and

Fig. 13.

Enamel prisms as they appear in relation to each other; from human tooth.

so on from the base to the apex of the prism. The whole fabric by this means receives great additional strength. But, as a structure, when completed it possesses less peculiarity in its conformation, by which its animal origin might be discovered, than any other formation of which the teeth are composed, or perhaps of any structure in the whole range of the animal kingdom above the mollusca, to the testaceous covering of which it has been compared.

4. The office which the enamel fulfils to the tooth is twofold: first, by its hardness, it precludes wearing from friction; consequently its presence will be found in all those animals in which the teeth form more important agents in the animal economy than mere prehensile organs; in some teeth covering the crown: in others it is again covered by a layer of osseous tissue (*crusta petrosa*), and only becomes exposed under the wearing influence of mastication. In the former class of tooth it fulfils a second purpose—that of protecting the dentine from the action of other external agents (chemical, &c.). To carry out this condition the enamel is peculiarly adapted, it being so closely built up that it is impervious to the most subtle fluid; and therefore, under normal conditions, no moisture external to the system can come into contact or act upon the more porous substance of dentine without previously destroying the enamel. Often has the experiment of saturating a tooth in common writing ink been resorted to as a test to show the porosity of its structure; but the evidence so obtained is most inconclusive, since all inks contain a certain quantity of acid: thus the appearance of saturation given to a tooth which has long been so immersed is due not to the porosity either of the dentine or enamel, but to the chemical action of the ink upon the substance itself.

5. The chemical composition of the enamel differs from that of dentine only in relation to the respective quantities of the component parts: thus it will be found that the true bone salt, the phosphate of lime, abounds in a greater proportion; while the organic matter and carbonate of lime are present less than in dentine. If a specimen of enamel which has been immersed for some time in ink be examined under the microscope, it will be found to be more or less equally over the whole

ternal surface; but upon cutting out a section from the deepest parts, where the action of the ink can only be seen upon the edge, it will be found that the chemical action of the ink commences first along the line which marks the boundary of each prism, and then across the diameter, at, I presume, the point of union between the several cells which unite to make up a single prism: that is, the chemical action takes place first upon the walls of the cells, as is shown in the accompanying illustration.

FIG. 14.

Enamel treated with common writing ink.

This is an interesting fact, and goes far to prove an assumption made in a previous paper, that the membrane of which the cell walls are composed ossifies through the agency of an amorphous salt of lime, which is probably the carbonate, which salt is much more readily soluble than the phosphate, and therefore first acted upon. First the cell walls yield to the chemical action of the ink, after which the contents of those cells; so ultimately the whole structure of the enamel becomes decomposed.

[To be continued.]

THE PULSE IN INFANCY.

ACCORDING to the statistical researches of Dr. Guy, the pulse in infancy varies with the sex.

The following table may, he considers, be presented as a fair average:—

	Males.	Females.
Under 2 years	110	114
2—5 „	101	103
5—8 „	85	93
8—12 „	79	92

It is thus uniformly quicker in the female than in the male, and the difference between the two at five years is very

AN ESSAY ON
UNHEALTHY INFLAMMATIONS.

BY M. BROCKE GALLWEY, ESQ.

Assistant-Surgeon Royal Regiment of Artillery,
Woolwich, Kent.

[Continued from p. 631.]

ERYTHELMA (continued).

Erythema and erysipelas very generally confounded by systematic writers—Difficulty of laying down practical rules of distinction between them—The author's definition of erythema—Asthenic nature of erysipelas in all its forms and types—This position disputed by some eminent authorities—ex. gr., Sydenham, Cullen, Dr. Andrew Duncan, jun., Lawrence—Mr. Lawrence's views of the pathology of the disease.

HAVING now disposed of that portion of the inquiry which has relation to the innate cause or essence of the disease, I proceed to the consideration of the second proposition with which I opened the subject of erysipelas—to wit, its “*immediate connection with an adynamic condition of the system.*”

If, in the prosecution of the first of these inquiries, I approached the subject with a distrust inseparable from the consciousness that its nature did not admit of demonstration, as well as from that of the difficulty surrounding it, I am discouraged in the present instance by no such embarrassing considerations; for, though I shall be thought by some practitioners to have mistaken Nature's meaning in the conditions of this inflammation, the *evidence* in support of my present proposition crowds fast and thickly upon us. The *nil quod non demonstrandum*, how applicable soever in the one case, can be allowed no “habitation” in the other, for, now our business is alone with demonstration. Before we enter, however, upon an analysis of this evidence, a question of some importance engages us *in limine*, upon which it is necessary we should have something like a definite understanding. That question is, *What is, and what is not, erysipelas?* The reader is aware that this is debateable ground, and that some of the fairest names in medicine—among the moderns

more particularly—have ranged themselves on opposite sides of the same. It is not my intention now to canvass the arguments that have been brought forward upon this vexata quæstio: I shall do little more than allude to their existence. But, it may not be a profitless task altogether, to adduce an example or two of the discrepancy of opinion to which I have adverted, and I shall borrow them from amongst the highest authorities in medicine.

It is to the confusion existing in relation to the terms *erysipelas* and *erythema* that I now more particularly invite the reader's attention.

Bichat and Dessault appear to recognise no independent existence for erythema. The former says of erysipelas—“*La première et la plus simple, et celle que Sauvages et Cullen appellent erythema.*”*

Bursarius, again (one of our best writers on erysipelas) makes no sort of allusion to erythema by such title, though he probably meant to describe that affection when he speaks of the “simple” form of erysipelas, as thus—“*Simplex quoque chirurgi illud nominant, quod nullo gravi aut periculoso symptomate stipatur.*”†

Pearson treats of erysipelas and of cedema-cum-erythemate as two diseases, and yet is very happy in his perfect fusion of, or confusion between the two.‡

Callisen describes erythema as the lightest of all forms of erysipelas, which perhaps is no unhappy definition of the disorder.§

The two Franks describe erythema and erysipelas as diseases as opposite to each other as the poles.||

Cullen lays it down that they are two disorders, and their phenomena connected with different orders of disease:—“When the disease is an affection of the skin alone, and very little of the whole system, or when the affection of the system is only symptomatic of the external inflammation, I shall give the disease the name of *erythema*; but when the external inflammation is an

* Œuvres Chirurgicales de Dessault par Bichat, tom. ii., p. 581.

† Institutionum Medicinæ Practicæ, &c., volum. secundum, p. 15.

‡ Principles of Surgery.

§ Systema Chirurg. Hadiern, vol. i., p. 483.

|| De Curandis Hominum Morbis, lib. iii. Præceps Medic. Univ. Præcepta, vol. ii. and iii.

exanthema, and symptomatic of an affection of the whole system, I shall then name the disease *erysipelas*.*

"The erythema is a nearly continuous redness of some portion of the skin, attended with disorder of the constitution, but not contagious. This appearance, though in general symptomatic, merits our attention, as it should be carefully distinguished from other eruptions, particularly from the contagious exanthemata." "The erysipelas is a febrile disease, in which some part of the body is affected externally with heat, redness, swelling, and vesications."†

Bateman is still more explicit:—"The word *ερυθημα*, as used everywhere by Hippocrates, signifies simply redness, and is therefore correctly appropriated to this affection, which differs from erysipelas, inasmuch as it is a mere rash or efflorescence, and is not accompanied by any swelling, vesication, or regular fever." Again—"The presence of tumor, together with vesication, distinguishes the disease (erysipelas) from erythema."‡

Mr. Hunter would appear to have considered the two diseases synonymous, if we may judge from the fact that he mixes up the symptoms of both in his first description of erysipelas, and makes no individual mention of erythema. Like Willan and Bateman, he describes *vesication* as a natural feature of erysipelas, though we shall presently see that a subsequent authority considers a peeling of the cuticle to be characteristic of erythema. He tells us that "the erysipelatous inflammation is very peculiar;" and that "most inflammations that are not of the true adhesive and suppurative kinds are called so, although probably they do not in the least belong to it." Mr. Hunter subdivides *inflammation* into a genus consisting of *five* species—viz., "the adhesive," "the cedematous," "the erysipelatous," "the carbuncular," and "that which leads immediately to mortification." And, while he tells us in one breath that "the erysipelatous inflammation is very peculiar," in another he remarks "it is probable there is no specific distinction between any of these inflammations but what arises from the constitution of the parts; for we find them all proceeding from what may be called the same accidental cause, which,

therefore, cannot produce anything specific."* Thus, while this classification of inflammations to myself appears both defective and contradictory, it is wanting, for our present purpose, in an intelligible definition of erysipelas, and makes no mention of the independent existence of such a disease as erythema.

Dr. Mason Good distinguishes, or fancies that he distinguishes, erythema from erysipelas by the following description:—"Erythema is local inflammation *tending to vesication*; erysipelas an idiopathic fever producing an erythematous efflorescence."* Erysipelas, he adds, is "occasionally" contagious; erythema has "no such tendency." Again, "This genus of inflammation" (erythema) has "been very generally confounded with an exanthem or eruptive fever (erysipelas) which, in one or two of its species, it frequently accompanies, but of which it is then a mere symptom."† It would not be difficult, I think, to point out the weak points of this accomplished physician's diagnosis, dogmatically as he insists upon its truthfulness: for instance, are we to understand that erysipelas never terminates by *vesication*; and that it is incapable of doing so because, forsooth, it is "idiopathic fever producing an erythematous efflorescence?" Why, upon this showing, scarlatina should be equally free from such termination, and so should typhus fever! And then, after falling foul of some of the best writers upon erysipelas (not sparing the incomparable Galen) for the confusion they evince between the two diseases, we find him betraying the inconsistency of introducing an "erysipelatous erythema" into his laboured classification of erythema (of which he makes out *seven* species), and of thereby himself acknowledging the family relationship, if not the identity between them: but, *allquando Homerus*, &c.!

Mr. Lawrence is altogether at issue with this view of the question. The two diseases (if I may be allowed the *Milesianism*) in his eyes are one and the same. "By erysipelas I understand in-

† The History of Medicine, by John Mason Good, vol. ii. p. 363, 4th edit.

‡ Ibid. vol. ii. p. 59.—Mason Good thus contends, with many pathologists, for the *exanthematous* nature of erysipelas, although its striking departure from the rule of that family of disease ("morbis contagiosis, *semel tantum* in decurrit: aliquem accitescent") is sufficiently well known.

* First Lines of the Practice of Physic, p. 274.

‡ Bateman on Cutaneous Diseases, pp. 118-25.

inflammation of the skin, either alone or in conjunction with that of the subjacent adipose and cellular tissue. Like other inflammations, it varies in degree. When it affects the surface of the skin,—which is red, not sensibly swelled, soft, and *without vesication*," (when doctors disagree, &c.!)—"it is called erythema." "As erythema, simple erysipelas, and phlegmonous erysipelas, are merely three degrees of the same affection, they ought not to be separated."* Mr. Arnott would limit the expressions erysipelas and erysipelatos to the *face alone*, as he looks upon the affection as peculiar to that region of the body, and as quite foreign to the nature of inflammations occurring in other parts of the external skin.†

One of the most classical writers of our own times upon this disease has sought to contract the conditions of erysipelas within a very narrow circle:—"Erysipelas is constantly confounded with inflammations of the integuments, which arise under different circumstances, and are of a distinct character. Thus the inflammatory oedema so commonly following the bites of leeches on the eyelids, prepuce, scrotum, and other cellular textures, parts much disposed to erysipelas; the sympathetic erythema, or even suppurative oedema, which takes possession of the integument of a limb, in inflammation of the fascia, veins, or absorbents, and in sub-fascial collections of matter; and the sympathetic blush of the skin covering a gangrene, as of the tunica vaginalis testis, or a mortified hernia, are denominated erysipelas, by which it is intended to designate an adventitious form of the disease. The state of the integument which results from the infiltration of the cellular membrane by an extravasated fluid, from sympathy with inflamed absorbents or veins, and from changes of the subjacent membranes, or accumulations of them, is widely different from erysipelas; and we should greatly reduce the list of cases classed and reported under this head in surgical practice if we would confine the term to those in which the skin, or skin and cellular membrane, are *primarily* affected." "Commencement in the integument, external or internal, deficiency

of adhesive inflammation, and a peculiar state of the system with which the inflammation is connected, whether spontaneous or the result of injury, are diagnostic characters of erysipelas."* And yet the terms of this definition might not be excelled in correctness if selected for an exposition of erythema, so great in reality is the difficulty of affording a verbal distinction between the two!

Andral is chargeable with the same want of precision in the looseness with which he employs erysipelas to characterise an erythematous blush of the integuments consecutive on a puncture in a dropsical individual. Hunter would have designated it "oedematous inflammation;" Mason Good "oedematous erythema;" Travers "inflammatory oedema:" while, in Andral's eyes, it is a true erysipèle. "Peu de jours après son entrée" (speaking of a patient's entrance into La Charité) "la ponction fut pratiquée: deux autres furent faites dans les trois semaines suivantes. Cependant, le malade s'affaiblissait, et son appétit avait diminué, lorsqu'à la suite de scarifications pratiquées sur les deux membres abdominaux considérablement oedématisés, une rougeur livide s'empara de la peau de la jambe droite; le troisième jour de l'apparition de cette rougeur, la peau où elle s'était manifestée était déjà frappée de gangrène; en même temps prostration rapide. Mort six jours après l'invasion de l'*érysipèle*."

"La mort fut évidemment le résultat de l'*érysipèle* gangréneux qui s'empara de la peau de l'une des jambes à la suite des scarifications. Certes, la terminaison de cet *érysipèle* par gangrène ne sera point ici attribuée à un excès d'inflammation."‡

Thus, among the distinguished authors whom I have quoted as having bestowed their attention upon this question (but who compose a small minority only of those who might be enumerated), we observe a remarkable disagreement as to the real distinctions between the two diseases,—one declaring that they are totally opposite in their characters and nature; another that there is no distinction between them: this pathologist laying it down

that vesication is the characteristic feature of erythema; that, that erythema differs from erysipelas in never vesicating: some declaring erythema to be a disease *sui generis*; others averring that there is no such affection at all!

They tell an anecdote of James the Second, that, having gone to Westminster Hall to hear the pleadings of eminent counsel, he was so bewildered by the confusions and contradictions of the *dramatis personæ* on that celebrated stage, as to have lost all patience and decorum, and exclaimed, "*Rogues all, Rogues all, to the De'il wi' ye, to the De'il wi' ye!*" I speak it not irreverently of their high mightinesses,—but what would the simple-minded monarch have conceived of the luminaries of our "craft," had he stepped in to a debate at the "Medico-Chirurgical," or, at the "Académie de Médecine" across the water, upon the question now in hand, and sought for information upon the same!

I might well be excused, then, for shrinking from a closer intercourse with this disputed point, and for leaving it in its present uncertainty. Nevertheless, I will venture to suggest the following brief outline of a definition of erythema, as offering at least an approach to a practical distinction from erysipelas.

A rash or efflorescence devoid of swelling, unattended by febrile movement, never suppurating, sometimes vesicating, sometimes not, unconnected with epidemic influences, and incapable of communication to others by contact or through the medium of the surrounding atmosphere.

I do not pretend to offer this as a definition by any means embracing all, or nearly all, the distinctive features of erythema, but merely as an enumeration of the salient points of the affection.*

* Those who may wish to prosecute this inquiry further, I may refer to Dr. Weatherhead's valuable Essay on the "Diagnosis between Erysipelas, Phlegmon, and Erythema;" as well as to the article "Erythema" in the viii. vol. of the "Dictionnaire de Médecine," by M. Rayer, where the diagnosis and natural history of the disorder are particularly well laid down, but which are deformed by the asserted connection of the same, at least in one of its forms—the "symptomatique"—with that ubiquitous monster endemic to the soil of French understandings—the *causæ-anterio!* "*L'érythème doit être combattu par les antiphlogistiques, quelle que soit sa forme; et par la saignée lorsqu'il est général.*" Ple on't! oh, fie, Monsieur Rayer! "There has been much throwing about of brains" among your countrymen in this matter!

Erysipelas essentially an asthenic or adynamic inflammation.—There is, happily, far less disagreement at the present day amongst the aristocracy of medical learning upon this question, than upon any of the preceding that I have examined in connection with this large and extended subject. With the great body of the profession, however, it is to be feared that it is still much the practice to regard it as an *healthy*, or, in other words, a common inflammation, and to administer heroic remedies for its relief. The favourers of this view of the nature of erysipelas may boast of the support of no less an authority than Sydenham, who was wont to bleed his patients largely under this disorder. "*Ubi primum accedo,*" says he, "*satis largam sanguinis quantitatem è brachio extrahi præcipio, qui quidem pleuritico-rum sanguinem ferè semper æmulatur.* Die sequente blandam illam potionem catharticam mihi in praxi familiarem exhibeo." Then follows an account of his local appliances, immediately after which he continues,—"*Hæc methodum febris, tum alia symptomata, citissimè ut plurimum fugantur.* Sin aliter, rursus venam seco; quod *et tertium* non nunquam fieri debet, interposito semper die uno, si prava nempe adsit sanguinis diathesis, et febris intensior."*

Cullen followed in the footsteps of Sydenham. "The erysipelas of the face," says this excellent physician, "is to be cured very much in the same manner as phlegmonic inflammations, by blood-letting, cooling purgatives, and by employing every part of the antiphlogistic regimen; and our experience has confirmed the fitness of this method of cure."† The same principles are enjoined in his "First Lines" (vol. ii. p. 392).

The same views have been strongly urged upon our notice by a writer of our own times, Dr. Andrew Duncan, junior, who, in the 17th volume of the Edinburgh Medical Journal, has published a series of cases of erysipelas, with the particular view of recommending free depletion for that disease. But, had not Dr. Duncan's *own detail* of those cases impressed me with a contrary view of the propriety of his practice in the same, I should have expected

* Observationis Medicæ circa morborum acutorum historiam et curationem. Febris Erysipelacea, p. 416.

† Practice of Physic, vol. ii. p. 268-8.

rienced grave suspicions on the subject, from a remark with which the paper in question sets out. "After the abundant experience we have lately had of the safety and advantage of venesection in many diseases in which it was formerly prohibited, especially in *continued fever, arising from contagion, in small-pox with typhus fever, and scarlatina with malignant sore-throat*, the extension of the same powerful remedy to another febrile disease, with cutaneous inflammation, seemed to be naturally suggested."*

We have another advocate of this view of the nature of erysipelas in the justly celebrated Dupuytren, who has lately been removed from among us. Nor am I acquainted with a happier instance than is to be found in this writer, of a complete *misinterpretation* of the pathology of the disease.

In a clinical lecture, delivered at the Hôtel Dieu, and subsequently translated for the *Lancet*, the Baron relates the particulars of four cases of what he denominates "Diffuse Phlegmon." The result of the first is not stated. The second presented such formidable appearances, that he seriously meditated amputation of the limb: the patient, however, recovered at the end of *three months* from the commencement of the attack. The third passed into a state of gangrene, but was saved after two months duration of the disease. The last died. These cases were all *largely bled and leeches*. That the reader may form his own idea of the Baron's management of particular symptoms, I shall subjoin a passage or two from his own words. *After gangrene had made its appearance* in the third case, he says

* P. 537-8.—In Dr. Duncan's second case, after *fifty-two ounces* of blood had been abstracted by the lancet, and as much more taken as could be solicited by forty-four leeches (not to speak of the collateral assistance of calomel, antimony, and jalap), the report, *ten days subsequent* to the commencement of this sharp practice, stands thus—"Erysipelas spreading down the back; and, on the following day, erysipelas continues to spread." Pp. 544-5. Some of the other cases manifest the same want of subservience on the part of the disease to the depletory measures addressed to them. But, Dr. Duncan's faith was strong in the charm of his specific, so strong indeed as to blind his judgment to the real truth of the matter: to wit, that the disease progressed in spite of the most determined application of his treatment; or, as I think myself warranted in assuming, as a consequence of that treatment. Yet, this physician was so fascinated by a theory, as to have published thirty pages of tolerably close print, whereby to introduce a misshapen offspring to public favour!

—"we immediately drew blood from the arm." "This patient continued delirious during the whole night; and the vomiting persisted to the morning: twenty leeches over the epigastrium." "On the third day the delirium had ceased, but the patient was excessively feeble: forty leeches to the thigh." The gangrene continuing to spread, the question of amputation was entertained: The erysipelas in this case ensued upon the operation of venesection in the foot; and, alluding to its severity, the Baron, after bringing the subject of it to death's door by depletion, with an artlessness deserving of a better cause, observes—"Having thus explained the unfortunate consequences of venesection, let us return to the causes of diffuse phlegmon." Finally—"The facts I have related have given you an idea of the character of diffuse phlegmon, of its danger, progress, termination, and the treatment which is adapted to it!"*

Though not strictly *à propos* to the present subject, yet, in connexion with one of the same family of diseases, I shall here indulge the reader with an agreeable and pertinent anecdote, by way of relieving the dulness of this matter of fact contribution. "The Princess Anne" (of Denmark, afterwards Queen of England) "kept the eleventh birth-day of her son, the Duke of Gloucester, with great rejoicings, little anticipating the result. The boy reviewed his little regiment, exulted in the discharge of cannon and crackers, and presided over a grand banquet. He was very much heated and fatigued, and probably had been induced to intrench on his natural abstemiousness. The next day he complained of sickness, headache, and a sore throat: towards night he became delirious. The family physician of the princess sought to relieve him by bleeding, but this operation did not do him any good. There was a general outcry and lamentation in the young duke's household that he would be lost, because Dr. Radcliffe was not in attendance on him, owing to the affront the princess had taken. Dr. Radcliffe was, however, sent for by express, and, though unwilling, he was prevailed on to come. When he arrived at Windsor Castle, and saw his poor little patient, he declared the malady to be the scarlet fever: he demanded who

had bled him. The physician in attendance owned the duke had been bled by his order. 'Then, said Radcliffe, *you have destroyed him, and you may finish him*, for, I will not prescribe.' The event justified the prediction of the most skilful physician of the age; but, he was as much abused by the people, who clung to the last scion of their native princes, as if he had wilfully refused to save the child.*

But the great champion of a depletory line of treatment in erysipelas in this country is Mr. Lawrence, whose work on the subject has so much influenced the views and practice of English surgeons in their dealings with this disease that I deem it necessary to devote some space to an analysis of the merits of that publication.

"Regarding it" (erysipelas) "as an affection essentially inflammatory, some adopt the antiphlogistic plan, including general and local bleeding; while others, conceiving that the part, the constitution or both, are in a state of debility, endeavour to remove this by the free use of stimulants and tonics, more especially by bark, ammonia, and wine. The former appears to me the correct view and practice. I accordingly consider the latter notion completely erroneous, and the treatment founded on it not only inappropriate, but injurious."

The foregoing passage will serve as a text to Mr. Lawrence's observations, the latter affording a striking and consistent commentary upon the same.

The reader, in consideration of the importance of the subject, will bear with me, I trust, whilst I summon Mr. Lawrence himself into court, and afford him an opportunity of pleading, *ipse dixit*, his own course.

"A consideration of the origin, development, and effects of erysipelas, of all its phenomena, whether local or general, leads us irresistibly to the conclusion that the nature of the affection is inflammatory. In its four leading characters of redness, swelling, heat, and pain, and in its effects of effusion, suppuration, and sloughing, it agrees with what is called common or phlegmonous inflammation; while the gene-

ral disturbance preceding and accompanying the local affection is often exactly alike in the two cases. Erysipelas, then, is merely a particular modification of cutaneous or cutaneous and cellular inflammation."

"The difference between erysipelas and phlegmon is not merely in the original seat or degree of the disturbance; there is also a difference in kind." "The most striking and important distinction between the two affections is, that inflammation is confined to one spot in phlegmon, and is distinctly circumscribed in its seat; while it is diffused in erysipelas, and spreads without limit." And then, explaining that this difference would appear to depend upon a lack of effused coagulable lymph in the latter, he continues—"We cannot at present explain the cause of this difference—that is, we do not know how it happens that coagulating lymph is poured out in the one case, and serum in the other. We are equally ignorant of the essential nature in many other modifications of inflammation which are yet obviously distinct. No one could overlook the differences between inflammation of the finger from a wound, that of whitlow, of chilblain, of erysipelas, of gout; yet, who could explain the differences of vascular action which cause these distinctions?"

"We must therefore admit, what even superficial observation will teach, that erysipelas is a *peculiar modification*—(this is *something*, at any rate, from Mr. Lawrence)—of inflammation in the skin and cellular tissue. I can, however, by no means agree with those who regard it as a distinct species of inflammation, and as capable in that character of affecting various parts of the body as well as the skin.*

Again: "I am quite at a loss to discover in this affection those marks of debility which some have so much insisted on. Erysipelas, like any other inflammation, may occur in old and feeble persons; and the effects of the disease, when aggravated by injudicious treatment, or protracted from any cause, will soon weaken the most robust; but, however weak the patient, the local disturbance is one of excitement: there is increased activity in the circulation of the part, clearly marked by all the symptoms. Indeed, speaking of the part, I

* *Lives of the Queens of England*, by Agnes Strickland, vol. xi. pp. 468-9.

† *Observations on the Nature and Treatment of Erysipelas*. By William Lawrence, Esq. *Med. Chirurg. Transactions*, vol. xiv.

* *Med. Chirurg. Trans.* loc. cit. pp. 17, 18, 19.

am unable to recognize debility as the cause of any inflammation whatever; and, in reference to the seat of disease, ~~to regard these expressions of passive and asthenic inflammation, and venous congestion, as either unmeaning, or calculated to convey erroneous notions.~~*

Without stopping at present to argue the latter point, (upon which, however, I venture to believe I could defeat Mr. Lawrence by many weighty facts and authorities), I have next to observe that our author, after stating that, "In attempting to establish the distinction between erysipelas and phlegmon, we perceive a fresh proof that they are not different in their essential nature" (p. 29), remarks upon its "causes" thus:—

"There is really no difference in this respect between erysipelas and other inflammations. The habitual excitement of the vascular system, or the long-continued disturbance of the stomach, alimentary canal, and liver, consequent on intemperance and excess, lays the foundation of inflammation generally, and it depends on individual peculiarity, or on local causes, whether the skin or other parts shall be the seat of disease" (p. 36).

[To be continued.]

DISCOVERY OF A NEW METAL. ARIDIUM.

M. UGGER has announced to the Academy of Sciences, of Stockholm, that he has discovered a new metal which he designates *Aridium*. It is found in the mineral chromate of iron of Reoras. Its oxides are analogous to those of iron, but they exhibit distinct reactions. The metal has not yet been obtained separately from its combinations with oxygen.—*L'Union Médicale*, Oct. 10th.

X

* Ibid. pp. 28-9. Mr. Lawrence would appear to have selected Dr. Andrew Duncan, Jun., (whose views on erysipelas he frequently quotes with much satisfaction,) as a model whereon to form his own views of inflammation. "I have long been inclined," says the latter, "to consider inflammation, upon whatever proximate cause it may depend, as identical in kind, and differing only in degree, or in respect to the texture or functions of the part affected; and that, with slight modifications, the same treatment is adapted to all." "I believe that there is no such thing as typhoid or asthenic inflammation, neither do I conceive that the disease differs in kind, or requires an opposite treatment, because it attacks a different texture, and is diffuse and erratic, instead of being limited and fixed."—*Edin. Med. Journ.* Loc. cit.

ON

RETENTION OF THE PLACENTA.

By B. W. Richardson,

M.F.P. and S., Glasgow.

THERE are in obstetric practice, as is well known, three causes of placental retention: the first arising from adhesion of the placenta to the walls of the uterus; the second, from an irregular contraction in some part of the body of the uterus, in which the placenta is grasped; and the third, from the contraction of the cervix uteri upon it while it is passing from the uterine cavity into the vagina. The first of these causes is least common; the second, more so; and the third, most of all. Of the first I do not wish to speak now as to treatment, but to state a simple plan which I have for some time past successfully been pursuing in practice for avoiding the occurrence of the two latter, and which I do not think has ever been employed before. It is this: Placing the patient in the usual position on the left side, I order, as soon as the head of the fetus is born, the hands of a nurse to be placed, the one over the uterus on the abdomen, the other on the back of the patient, and direct her, as she feels the uterus sinking into the pelvis and becoming smaller, to follow it up with firm grasping pressure. Then, in aiding the delivery myself, after the shoulders are delivered, and the danger past of the perineum being torn, I support the born part of the child with my right hand, and, passing two fingers of the left hand on to the body of the infant, seize the cord about three inches from the umbilical opening, and make gentle traction downwards as the remainder of the child is expelled, by which process the placenta is made to descend from the uterus with (i. e. immediately after) the feet, and so into the vagina before the uterine contractions entrap it. By this simple procedure I always ensure a safe and rapid delivery of the placenta, when there is no adhesion, and when the head presents; and since using it I have never had the placenta retained by contraction, with one exception, though I have often felt the uterus irregularly

contracted when empty, as in the second case related by Mr. Kirk.*

The operation is most easily done, is attended with no risk to the child, nor is the traction required such as to cause the least danger of tearing the cord; while, at the same time, the external pressure alluded to is an excellent means for keeping up the contractions of the uterus, and for preventing hæmorrhage.

In conclusion let me add, that I was led to adopt this plan by observing that in numerous cases, when the cord was folded round the neck of the child, the placenta was always expelled at once; and as I could only account for this by supposing that traction had thus been accidentally made, and had drawn down the placenta, I determined that in the next case where the cord was natural, to make gentle traction as described. The trial was very successful, and has been since so often successfully repeated, as to lead me to think that, were the system universally adopted, the introduction of the hand through the vagina would never be needed but in cases of adhesion, and that thus our fair patients would often be relieved from what is always a painful operation, be it performed ever so expertly and delicately.

Sept. 20, 1890.

CASE OF BIRTH AFTER THE DEATH OF THE MOTHER.

DR. SCHNEIDER relates, that being summoned in haste to a woman in labour, he found her dead on his arrival. On placing the hand on the yet warm abdomen, he felt the uterus contracted and sunk in the pelvis. By an examination per vaginam, a foot was detected, and by rapidly completing the delivery he had the satisfaction of bringing into the world an apparently still-born child, which, however, soon revived.—*Casper's Wehenschrift*.

* Dr. Schneider also cites instances, from the German journals, of the expulsion of the ovum at some distance after death, and when even putrefaction had occurred. Is it not probable, however, that the phenomena were due to the pressure exerted on the then soft and yielding uterus by the gases liberated in the intestines, as the result of decomposition? X

ON THE FREQUENCY OF THE ESCAPE OF THE LUNGS

IN GUN-SHOT WOUNDS OF THE THORAX.

By E. H. A. HUGHES, Staff Surgeon.

Vulnera thoracis.—Here we mean only very briefly to advert to the frequent escape of the lungs in small gun-shot wounds of the thorax. At Kilat, for instance, in November 1839, where the ordinary ball was that of the small rifle matchlock, we had twenty-one through the chest in the 2d, or Queen's Royal, then about 800 strong. Of these ten or eleven proved fatal immediately, or within a very short period. Among the immediately fatal was that of an officer, Lieutenant Gravatt (a very old and intimate friend), in whom the ball entered a little above the right nipple; but of the rest, only one proved fatal even eventually. In this a crepitating rale was distinctly audible next day in the vicinity of the wound, when first examined with the stethoscope, and which rapidly extended as from a centre till about the third day, when he died; but in none of the others could anything abnormal be detected in the murmur, though, from the site and direction of the wounds, it seemed almost impossible for the lungs to have escaped. One, too, an officer, was expectorating even frothy blood when first seen, yet he also recovered, without a single bad symptom afterwards, and is still in the corps. It may not, however, just be admitted that, because no crepitating rale followed, therefore there was no wound of the lungs, as that would but indicate at most a consequent pneumonia. Nevertheless, we implicitly relied upon this, and in every case the prognosis was fully verified by the results. At Ghuznee, however, what seemed only to be a wound of the thoracic walls soon afterwards proved fatal, and very unexpectedly; but, as the stethoscope was not made use of on this occasion, it bears less upon the point. The ball had penetrated directly through the breastplate; and, after being traced round by the emphysematous crackling and lividity, was cut out about the scapula, but the piece of the plate was not found. It is therefore possible that it may have

lodged where the ball first diverged, and eventually found its way into the thorax. We were ourselves then at Caubul, nearly a hundred miles off, but understood he had suddenly become very ill, and died shortly after. There was, I believe, no autopsy.

Also in our jungle sports in the East we were frequently disappointed with these gun-shot wounds of the thorax; for this, in the larger carnivora, was my favourite aim, and that of many others at my recommendation (for who should know so well as the doctor?); the smaller size of the head, and the strength and obliquity of the cranium in these animals, rendering that, as we thought, very uncertain. On one occasion we had to put no less than five balls (about musket bore) through the chest (most of them quite through) of a royal tigress before she was finally settled; and on another occasion a royal tiger went off as if untouched after two balls, though it was subsequently discovered that one of them had transixed him, as it were, from the right hypochondrium to the left axillary region, where it was found under the skin quite in a pool of blood. The other ball was in the liver.

Comparing these with the results of gun-shot wounds of the head, abdomen, and pelvis, we do think the thoracic organs, and particularly the lungs, are the least vulnerable parts of the body, but when wounded are more frequently followed by fatal results than even they are assumed to be. Taking, for instance, again, the 2nd, or Queen's Royal, at Kilat, the balls and other circumstances being equal: in six wounds of the head five proved fatal; of nine of the pelvis eight (the only recovery an officer, in whom the ball passed through the os ilium from in front without wounding the peritoneum), and every one of the abdomen. Those of the head were immediately fatal, as were those of the chest generally: those of the abdomen and pelvis within eighteen or twenty hours.

Bristol, Oct. 5, 1850.

CASE OF INDURATION OF THE BRAIN.

M. DUFLAY has communicated to the Biological Society of Paris the following case:—

— Vautier, aged 41 years, was admitted on the 22d June, 1849, into the Hospital of Incurables. He had complete paralysis of the lower extremities, and the

superior extremities also were weak, and their movements feeble and uncertain. His intellect seemed unimpaired: he understood what was said to him, but had difficulty in articulating.

His history was as follows:—He had always enjoyed good health until the spring of 1839. He was strong, and had followed the trade of a locksmith. He had not been addicted to excess in drinking, but he had not been equally prudent as regarded sexual gratification. In the course of 1839 he frequently experienced numbness of the lower extremities: these became during the same time weaker. Walking, at first uncertain, became more and more difficult, until he was obliged to have recourse to crutches. At the end of two years he had completely lost the use of both limbs. Caution, moxas, and all other means, were employed without avail. In the course of the next year a difficulty occurred in speaking, and in a short time he became almost unintelligible. The sphincters had also become paralysed.

In October 1849 he was admitted into the Infirmary, suffering from pericarditis and pleuritis on the left side, from which he recovered in the course of fifteen days, although his system received a severe shock from the additional maladies.

The morbid condition which he presented while in the Infirmary, and which remained until the day of his death, was as follows:—His legs were flexed on his thighs, and these on the pelvis; the prominence of the flexors over the extensors was so great, that, if the limbs were extended, they suddenly returned to the flexed state; the sensibility of the surface was not impaired; the senses and the intellect also retained their integrity. The patient gradually became weaker, and sank from the effects of profuse suppuration from ulcers of the integuments on those parts exposed to pressure. He died on the 23d November, 1849.

Autopsy.—The cerebral arachnoid presented a slightly opaque appearance. There was a small quantity of serous effusion beneath the arachnoid. There was no alteration in the grey substance of the brain. The outer third of the white substance was also unaltered; but, of the next two thirds, in proportion as the ventricles were approached, the substance was so much indurated that it was difficult to tear or crush it with the fingers. This portion of the brain had lost its whiteness, and had become of a dull yellowish colour. The optic thalami and corpora striata had undergone the same induration, but in a less degree, as also the Pons Varolii. The spinal cord appeared to be atrophied.—*Gazette Médicale.*

X

MEDICAL GAZETTE.

FRIDAY, OCTOBER 25, 1850.

At a meeting of the Middlesex magistrates, held on the 17th instant, a resolution was moved by Mr. Armstrong to the following effect.—

"That the Court is of opinion that measures should be taken for the substitution of a fixed salary in lieu of fees to the Coroner, and for the appointing of a medical officer to the Coroner's Court for the purpose of post-mortem examinations."

In support of this proposition, Mr. Armstrong stated that the practice of remunerating coroners by fees upon the number of inquests held was highly objectionable, since the power of determining when an inquest was to be held was exclusively in the hands of the officer who was the recipient of the fees. Although there are many honourable exceptions, there can be no doubt whatever that this mode of payment leads to the holding of more inquests than are absolutely necessary. As a confirmation of this view, it was stated that, since the inquiry out of which the present motion had arisen, there had been a marked diminution in the number of inquests in the county of Middlesex. We have no hesitation in stating our belief that, in thirty per cent. of the sudden deaths, inquests would be found entirely unnecessary if a proper medical inquiry were made into the circumstances attending death. The natural causes of sudden death are now very well understood. In the days of Edward I., when the law regarding inquests first came into force, "sudden death" uniformly implied the dagger or poison. Acting upon the ancient statute, many coroners have persisted in holding inquests upon cases which any expe-

rienced medical practitioner would have pronounced beforehand to be merely cases of death from natural causes—poisoning being impossible, either from the nature of the symptoms, or from the circumstances under which death took place. Of course, in a case involving the least degree of suspicion, there should be an inquiry: nothing less than this will satisfy the demands of justice, or clear the characters of persons unjustly suspected of having caused the death: but an exception of this kind certainly does not apply to numberless inquests in which verdicts of "death from apoplexy," "death from natural causes," "from the visitation of God," and of "found dead," are returned. The inquest is held; medical evidence is not required, or a neighbouring practitioner is called, but is not permitted to make a post-mortem examination, as it is deemed unnecessary; and the coroner and jury are quite satisfied without putting the witness to the trouble, or the county to the additional expense. How a really mysterious case of sudden death is to be cleared up, and the public justice of the country be satisfied, by such a mode of proceeding, we are at a loss to comprehend. These are the unnecessary inquests which the motion of the Middlesex magistrate, if ultimately carried, will assuredly clear off, to the great relief of the County rates.

The Coroner is, we believe, the only judicial functionary who is now paid by fees on the cases which come before him. He certainly is the only judge who can create cases for his own court; and is at the same time paid a certain sum per case. This is surely a strange and ridiculous anomaly in our criminal jurisprudence: it places an honourable man in a very unsatisfactory position, and it throws a great pecuniary benefit into the hands of one who may not be over scrupulous in the selection of cases for inquiry. Let us imagine that a

County Court judge is paid in a similar way, and we shall soon perceive the gross absurdity of the present system of remunerating coroners. A parochial rumour reaches the ears of the clerk of the County Court that A owes a certain sum to B, and will not pay him. The judge directs inquiry to be made, finds that the report is well grounded, and compels B to come into Court to prosecute his claim. Litigation would then be compulsory on all creditors in order that the judge might receive his fees. We admit that criminal differs from civil jurisprudence in the mode in which it is carried out, and in which it affects individuals; but the difference is certainly not of that nature to require a different mode of payment to the judges. A metropolitan magistrate is not paid so much per case for the cases brought before him,—sometimes the same cases as those actually under investigation by the coroner; and there is not the smallest reason why the latter functionary should not, like the magistrate, be paid by a yearly stipend. Common sense is in favour of the change; and we have reason to believe that it is strongly advocated by many coroners whose names are honourably known to the public.

It is proposed, however, to carry further this reform of the Coroner's Court. It is suggested, that instead of employing medical practitioners indiscriminately, and paying them a certain fee for each post-mortem examination, it would be better to appoint a *Medical Officer* at a fixed salary, whose duty it should be to superintend all post-mortem examinations in the county. In the opinion of Mr. Wakley, one medical officer, by a proper arrangement, would be able to make all the post-mortem examinations which the coroners of the county might deem advisable. We have no means of ascertaining correctly the number of inquests held yearly in Middlesex; but the post-mortem examina-

tions, unless the inquests be greatly reduced as an effect of the change, are not likely to be fewer than six hundred per annum. This would be a very laborious office, for any one individual: it could only be held by a man of experience, and would therefore require a high salary, with provision for an assistant. Nothing is said respecting chemical analyses; but it is not probable that any one would be found with the experience and ability requisite for conducting these, and at the same time of making the numerous post-mortem examinations required by all the coroners of Middlesex.

Another excellent suggestion is, that the inquests, instead of being held in low taverns or inns, should be conducted with all due formality in buildings or rooms set apart for the purpose. In the metropolis the court might be held, with greater convenience to all parties, in the vestry-room of the parish; and in the provinces, if not in the vestry-room, at the police station.

The proposition for thus reforming the office of coroner, at the recent Magisterial meeting, met with only two supporters. One magistrate, who thought *sufficient data* had not been put before the Bench for their guidance, moved the following amendment to the resolution, and this amendment was carried by a majority of ten:—

"That it be referred to a Committee to consider whether it would be for the benefit of the county that any and what different arrangement should be made for the performance of the duties now devolving upon the coroners, or respecting the remuneration annexed thereto, and to report their opinion thereon to the Court."

This is a quiet and respectable attempt to postpone the matter *sine die*; but we think it must fail. The magistrate who moved the amendment, and who talks of there not being "*sufficient data*," &c., can know little or nothing

about coroners' inquests, or the mode in which they are conducted. The abuses which it is proposed to remedy have been for years the subject of disgraceful contests between magistrates and coroners, and of unseemly disputes between these officers and medical witnesses. Every grown person in the habit of reading the newspapers is well aware of the necessity of a change; but the magisterial opponent of reform in the coroner's court either does not indulge in this habit, or, like Rip Van Winkle, he has just awakened out of a long slumber, and is wholly ignorant of what has been passing around him.

We hope that, now the subject has been mooted, it will not be allowed to drop. The proposition of Mr. Armstrong contains the germ of an excellent measure of reform—one which we think will be satisfactory to coroners, to medical practitioners, and the public. If carried out in a proper spirit it cannot fail to improve the administration of criminal justice.

We have received the following letter in reference to some remarks lately made in this journal on the new patent process for poisoning the public by sugar prepared with subacetate of lead:—

"Sir,—I read with great interest the letter of Mr. Herapath, and your remarks upon it, in the No. of Sept. 20, 1850, p. 518. Your two conclusions seem quite legitimate. This infinitesimal quantity (1-500,000th part of carbonate of lead), according to Mr. Herapath, was quite sufficient to endanger health; and, secondly, Mr. Herapath has done good service by showing how minute a quantity of lead will affect human health. With these two deductions, legitimate, I think, from the premises, I cannot reconcile the statement with which you conclude the notice of the election of the medical officers to the Hahnemann Hospital—"If Hahnemann's principles be ~~not~~ ^{fully} carried out in the new Hospital in cases of acute disease, we predict that the emoluments

of the coroner for Middlesex will be very considerably increased."

It seems, indeed, strange that Mr. Herapath's skill in detecting the action of an infinitesimal quantity of lead on a person should be recognised, and the discovery by homœopaths that the action of medicines in infinitesimal quantities upon diseased states should be condemned; and that Mr. Herapath should be regarded as having done good service by showing how minute a quantity of lead will affect human health; and homœopathic practitioners, for using infinitesimal doses, which they find will affect human diseases, for the cure of those diseases, should be liable to the tender mercies of Mr. Wakley, and should be considered as fit game for the coroner.

This latter conclusion of yours seemed the more extraordinary, because the whole tenor of your valuable journal is to show the incompetence of the non-professional public to judge medical questions; and yet here you write, approvingly, of submitting a question of medical treatment to twelve jurymen.

A SUBSCRIBER AND CONSTANT READER.

We must inform our friendly monitor that he has committed several notable errors in endeavouring to draw an argument in favour of the efficacy of homœopathic doses from Mr. Herapath's observations on the action of lead in river water, and from our comments on his letter. It is not implied that each person took one half-millionth of a grain of lead, and suffered any observable symptoms from this dose. On the contrary, it was to the constant use of this water, containing *one grain of lead* in nine gallons, and to the well-known accumulation of this metal in the system, that the injurious effects of lead were due. The same would happen whether the lead were prescribed in this dose homœopathically, or taken accidentally, provided it were frequently repeated for a considerable time. The writer of the above letter leaps to an extraordinary conclusion, if he considers that a *decillionth* taken at one dose will be as potent in its effects on the system

as a half-millionth proportion of the carbonate of lead diffused through water which is continued daily for weeks and months together,—the lead acting not by its small proportion, as contained in the water, but by its special accumulation in the system. The effects of these small doses of lead are often not manifested for many months, and then only by their aggregation. In homœopathy it is pretended that a special effect is produced in a few hours by a globule containing only a millionth-millionth part of a grain of something,—*e. g.*, charcoal, sulphur, or Cayenne pepper, which in the dose of a grain is without any action on the body! This is obviously a gross and barefaced assumption, not only insusceptible of proof, but in complete violation of common sense. It is, when men pretending to medical knowledge, give what they profess to be billionth and decillionth doses, to persons labouring under acute diseases, requiring the active and immediate application of visible and ponderable remedies, that we think a coroner's jury justified in inquiring into the cause of death, and whether the patient has not fallen a victim to positive neglect. We cannot look upon the "globule" system as *medical* treatment, and herein we wholly differ from our correspondent. We defy him to prove that there is *any* medicine in any one globule prepared *bonâ fide*, or that there is any demonstrable difference in any two globules labelled differently. A homœopathist treating a case of pneumonia according to the globular system, resembles an orthodox practitioner who professes to treat it with pills of *mica panis*. In the event of death in either case, there should be a coroner's inquest.

Reviews.

A Theoretical and Practical Treatise on Human Parturition. By H. MILLER, M.D., Professor of Obstetrics and the Diseases of Women and Children in the Medical Department of the University of Louisville. 8vo. pp. 468. Louisville: Cowling and Davies. London: Delf. 1850.

On the Theory and Practice of Midwifery. By FLEETWOOD CHURCHILL, M.D., M.R.I.A., &c. &c. 2d edition, corrected and improved. Small 8vo. pp. 496. London: Renshaw. Dublin: Fannin. 1850.

We here bring under the notice of our readers two works on Obstetrics, from the pens of authors deservedly celebrated, in their respective spheres, for their practical experience and scientific attainments. We may therefore, with advantage, take the opportunity to compare on a few points, as the tests of the whole, the present state of obstetric science in the American, and in the British, schools of Midwifery. We institute this comparison entirely free from national prejudice, our object being to show, that, in every branch of the Anglo-Saxon family, the arts and sciences which benefit mankind are equally progressive, and are equally adorned by their professors.

As our readers may probably not be so well acquainted with Dr. Miller as with Dr. Churchill, we shall take the liberty of introducing him in his own words, adding, that, for his works more than for his words, they will do well to cultivate his acquaintance.

"You are to know, indulgent reader, that the author of the work you are now peeping into is a man rather advanced in life (though you need not be precisely informed of his age—that is a delicate point*), who has seen much and read some, touching the subjects he proposes to handle; and has withal been accounted qualified to teach others what it has been his chief pleasure to practise, since he was a very young man. He loves his

* So "delicate" a point is this among our American brethren, that lately, having an American lady under our care whose age it was of some importance to know, we were informed by her husband that he did not know his wife's age. That it would be received as a gross affront to ask the age of any individual, male or female, in the United States!

vocation, notwithstanding the difficult and important duties it imposes, and would not exchange it for any other; to this attachment, more than to superior capacity, he honestly ascribes whatever proficiency or eminency he may have attained in it. Reader, if you have not this love, you have mistaken your calling. For the rest, the author is a backwoodsman, having been brought to light in Kentucky by a process which it is his purpose to unfold in this treatise. His education was not acquired in academic halls, but in the primitive school-houses of his native state, and upon the ample sward, shaded by forest trees, appurtenant thereto: so that, you see, he was reared after the fashion of Socrates, imbibing knowledge in the schoolhouse under the shade of trees, and not unfrequently perched upon their boughs." (*Preface*).

Dr. Miller states that the aim of his book is no lower than to establish a classification and nomenclature for foetal presentations and positions. The classification which he recommends is that of M. Dugès; the nomenclature is his own. His principles of practice are those of Hamilton and Burns; and although the author considers that by this confession of his principles he incurs the application of the epithets "officious" and "meddlesome," we think that no person who carefully studies Dr. Miller's work will be warranted by his own experience (if he have any) in lightly making such a charge.

The subject of Dr. Miller's work is then, as just stated, the process of parturition; with especial reference to the nomenclature of midwifery. It contains, first, observations on the obstetric characters of the pelvis; and the obstetric aptitudes of the foetus and its appurtenances, the membranes, placenta, &c. The description of the phenomena of labour is preceded by the consideration of the structure of the uterus, its muscular and nervous systems, as expounded in Dr. Robert Lee's investigations, "who," in the words of Dr. Miller, "has laboured more successfully in this branch of obstetrical anatomy than any of his predecessors." The cause of labour is next considered at some length by Dr. Miller; this, which Dr. Churchill observes, "all search has failed to discover," is supposed by Dr. Miller to be explained by "irritation of the cervix, and especially of the os uteri, arising from the contact of the ovum with it,"—a theory, however, which, Dr. Miller remarks, originated with Dr. Power.

Labour is divided by Dr. Miller as by most authors, into three stages. The consideration of the management of these is succeeded by that of the various presentations and positions of the foetus, and of their several and particular treatment. The conduct of the third stage of labour, and of asphyxia neonatorum, of morbid retention of the placenta, and of uterine hæmorrhage, concludes Dr. Miller's work.

Our readers are familiar with Dr. Churchill's name, as that of an obstetric authority of high reputation, founded on the soundness of the principles of practice which he has taught, and upon the extent and accuracy of the statistics on which he has based the theoretical deductions, or whence he has drawn his practical conclusions. Many also among our readers are, we doubt not, acquainted with the first edition of Dr. Churchill's "Theory and Practice of Midwifery." The author's object in the publication of that work was "to offer to the student a work embracing the modern discoveries in the physiology of the uterine system, with all the recent improvements in practice, in a condensed form." That this object was fully attained has been affirmed by the general voice of the obstetric department of the profession. That the second edition has in no degree departed from the "object" of the first, we take upon ourselves to affirm. No improvement in practice has been overlooked, and no mere innovation, of any importance, has been suffered to pass unrebuked. We are disposed to make one single exception to our remarks here. Dr. Churchill approves of the employment of anæsthetics in labour, we think, on insufficient grounds. As we have, however, on former occasions, fully expressed our own views on this question, we shall dwell upon it no further at present. We would add that the illustrations, which are abundantly furnished, are both apposite and well executed.

Dr. Churchill divides his work into three portions:—

1. The anatomy of the pelvis and organs of generation.
2. Of the physiology of the organs of generation.
3. Of parturition.

With a *parallel* we have over the two *first* *Churchill's work*.

simply observing that they contain a very large amount of valuable information on the points of which they treat. We shall confine our attention to the third division, which is concerned more exclusively with the process and management of labour in all its varied forms, natural and preternatural.

We notice in the first place the more especial object of Dr. Miller's work—the nomenclature of midwifery. The classification of parturition adopted by both the authors before us does not differ much. Thus Dr. Miller adopts that of M. Dugès, which admits *five genera and fourteen species*; by *genera*,

meaning presentations, and by *species*, positions. The *back* of the fetus serves as the point of comparison, and is placed anteriorly or to the left, in the first species of each genus—posteriorly or to the right, in the last.

Dr. Churchill arranges every variety of *presentation* under four heads, and adopts M. Naegle's classification of *positions*.

We have placed the classification adopted by the authors in juxta-position, to show their points of resemblance and of difference. These varieties are, by both authors, arranged in the order of the frequency of their occurrence.

MILLER.	
GENERA. Presentations.	SPECIES. Positions.
I. Vertex.	1. Back anterior and left. 2. Back anterior and right. 3. Back posterior and right. 4. Back posterior and left.
II. Pelvis.	1. Back left. 2. " right. 3. " anterior. 4. " posterior.
III. Face.	1. " left. 2. " right.
IV. Right shoulder.	1. " anterior. 2. " posterior.
V. Left shoulder.	1. " anterior. 2. " posterior.

CHURCHILL.	
Presentations.	Positions.
1. Head.	1. Posterior fontanelle to left foramen ovale. 2. To right foramen ovale. 3. To right sacro-iliac synchondrosis. 4. To left sacro-iliac synchondrosis.
2. Breech, including the hips and loins.	1. The back of the child, anteriorly.
3. Inferior extremities, including the knees and feet.	1. The toes directed backwards. 2. Do. forwards.
4. Inferior extremities, including shoulder, elbow, and hand.	1. Back of the child, anteriorly. 2. Do. posteriorly.

The following quotation from Dr. Churchill's work will show that it is more easy to classify positions and presentations at the study table, than to detect their diversities at the bed-side. With reference to head presentations, this author remarks:—

"There is a great difference of statement, however, as to the comparative frequency of the *second* and *third* positions; thus Naegelè, in 1290 cases, only met with the second position in *one* instance, or in the proportion of .07 per cent. M. Halmagand describes it as occurring in 5 per cent.; Madame Boivin in 19 per cent., and Madame Lachapelle in 20 per cent. On the other hand, Naegelè found 359 cases of the *third* position in 1210 cases, or 29 per cent.; while Madame Lachapelle gives only .077 per cent. of such cases, and Madame Boivin only .06. Dr. Simpson observed accurately the positions in 336 cases of cranial presentation; and found the first

position in 256 cases, the second in 1, the third in 76, and the fourth in two cases.

"It is extremely difficult to explain these discrepancies satisfactorily. M. Naegelè conceives that the examination was not made until after the change from the third into the second position had been effected; and he thinks that this opinion is confirmed by the fact that the frequency of the second position of authors agrees with the frequency with which he has observed the head to present in the third position."

Dr. Churchill concurs in this opinion.

We may in the next place compare the authorities before us, on the operation of *turning* or *version*, it being one requiring some judgment in determining upon its adoption, and skill and care in its performance. Both authors are agreed upon the most favourable moment for the attempt—that is, when the os uteri is fully, or nearly fully, dilated, and the membranes are still entire, or

as soon as possible after the rupture of the membranes, before the presenting part shall have become impacted by the uterine efforts into the upper strait.

Dr. Churchill advises that where the membranes have been ruptured for some time, as is often the case before additional advice is obtained, and the soft parts of the woman have become hot, dry, and tender, and in an inflamed and tumefied state, that recourse should be had to bleeding or opium, or to the employment of tartarized antimony, as recommended by Dr. Collins, of Dublin. Dr. Miller, as we understand, counsels turning at an early period to avoid these ill effects, and in this opinion we feel disposed to concur. Dr. Miller recommends, with reference to the position of the patient in turning, that the patient be placed

“across the bed, upon her back, and with the hips so near the side of the bed, that the perineum projects a little over the mattress on which she lies. Her feet may rest on chairs, or in the laps of two assistants, who are charged with keeping her knees far enough apart to make room for the operator to stand or sit between them. A sheet or blanket, according to the season, must be thrown over her to screen the patient from exposure, which is as indelicate as it is unnecessary; for the operation from first to last is to be performed under the guidance of touch alone.” (p. 396.)

This position is not advised by Dr. Churchill; it is not one which we should be disposed to adopt, neither is it generally, if even, ever, employed, in British obstetric practice. The position on the left side is preferred with us, as in ordinary labour; it has the advantage, besides that of having a more decent appearance, of admitting of more free motion of the operator's arm in following the axes of the pelvis, and adapting itself to the positions of the child.

Dr. Churchill does not give explicit instructions as to the choice of the hand with which the operation is to be performed; we therefore infer that he intends the right hand, as in ordinary labour, in conformity with British practice generally.

Dr. Miller, however, lays down the following rule:—

“The right hand must be used for the right shoulder, and the left hand for the left shoulder. When there is obscurity or uncertainty as to the presentation, the right

should be preferred, because it is that which most persons are accustomed to employ, and can, therefore, use with the greatest facility.”

Dr. Miller attaches considerable importance to the choice of the hand in turning; he observes:—

“The choice of a hand for the operation implies a perfect knowledge of the presentation, which ought, in fact, always to be attained, whenever it is practicable. This is the more necessary where the uterus is in a contracted state, as by guiding the hand in the right direction, namely, towards the feet, we shall be saved a deal of toil.”

Diversity of opinion exists as to the best method of bringing down the feet when they have been reached. By some authorities, delivery by turning has been advised to be completed as a perfect breech presentation; others recommend that the knees only should be brought down; while again it has been proposed by Dr. Radford “to bring down one foot only to save the trouble and difficulty of seeking for the other; and inasmuch as the breech with the thigh turned up is more bulky than the hip with the leg extended, by so much the passage will be the better prepared to admit the quick transit of the child's head, upon which the safety of the infant depends.” (Dr. Churchill, p. 269.) We have ourselves found this statement to be practically trustworthy. Dr. Churchill observes, in reference to arm and shoulder presentations:—

“The turning of the child is accomplished *during an interval of pain, the feet being brought over the front of the child, and not over the back, which would risk dislocation of the spine; and as the feet are drawn down the hand will ascend.*”

From this extract, the use of the word *feet*, which we have marked by italics, indicates the author's practice, which corresponds with that of Dr. Miller. There are of course cases in which either of these physicians would content themselves with bringing down one foot only.

Connected with the subject of turning, it may be proper here to notice Dr. Churchill's condemnation of Dr. Simpson's proposal, lately published in the Provincial Medical and Surgical Journal, to substitute turning as an alternative for craniotomy and the long forceps in deformity of the brim of the pelvis. Although this proposal has been made known through the pages of the Provin-

cial Journal; with the exception of Dr. Radford's criticism in the pages of the same journal, Dr. Collins's letters to Dr. Simpson, and the remarks of Dr. Churchill in the work before us, we have met with neither examination nor disapproval of this monstrous proposition (which, by the way, has not even originated with Dr. Simpson, although he does not state that he is indebted to Velpeau for the idea, as stated by Dr. Churchill.) We quote a few remarks from Dr. Churchill on this matter:—

"Now let us examine into the practical application of his proposal. The bi-mastoid diameter, in the six cases of measurement he gives, varied from $2\frac{1}{2}$ in. to $3\frac{1}{2}$ in.; and a living child can pass through a pelvis of $3\frac{1}{2}$ in. antero-posterior diameter, with or without the forceps. With a pelvis of this size the operation is then unnecessary; and if the antero-posterior diameter of the pelvis be less than $2\frac{1}{2}$ inches, the operation would be impracticable. Then these are the limits of the operation: for us to attempt to drag a child through a smaller space would be unjustifiable. For the success of the operation, then, we must be able to ascertain that the pelvis is within these limits, and perhaps in some few cases, with whose former labours we are accurately acquainted, we may do this, but in an immense majority of cases it will be, I think, impossible; and it happens, as Dr. Collins has shown, that the greater number of cases of difficult labour he met with were first cases, in which, of course, no such precise judgment could be obtained." (p. 263.)

Dr. Simpson would have it to appear that he has supported his views by statistics taken from the works of Dr. Collins and Dr. Robert Lee; but, as Dr. Churchill observes, he has done this "without sufficient care and caution." Certainly Dr. Simpson has adduced no experience of his own in support of this extraordinary proposition, beyond the relation of *one* case, and the loose statement that he has acted upon it "in other instances in which the head of the child had been morbidly detained at the brim, from the existence of a disproportion between the two." Beyond hypothetical reasoning on the dimensions of the pelvis, on the capability of the head of the fetus to suffer compression, on the capability of the child's neck to bear traction, and on the dangerous effects of duration alone of labour as far as the mother is concerned, we discover nothing in Dr. Simpson's papers which

have the slightest pretensions to be regarded as proved facts, in support of his proposition.

Dr. Simpson has, however, applied to Dr. Collins for his opinion of his proposed practice: we have a copy of Dr. Collins's answer, from which we make the following extract:—

"The first statement I shall notice is the *partial*, and consequently *erroneous* calculations, you have given from my work, withholding the *total mortality*, as well as the *cause* of the fatal result in *every case* of protracted labour met with out of the vast number of sixteen thousand six hundred and fifty-four births minutely recorded by me. Surely this is a great omission on your part; and thus, as you so justly condemn in others, you have drawn your deductions 'not from the *whole* of the practice, but from parts only: you have not reckoned upon the certain results of the *general* collection of facts, but depended upon the fallacious results of isolated and individual instances.'"

So much, then, for the statistics which Dr. Simpson borrows in order to support his new line of practice, which consists in dragging a child's head *vi et armis* through a contracted pelvis, almost to the certainty of decapitating the child, and the infliction of fatal injury upon the soft parts of the mother's pelvis.

But we again quote Dr. Churchill on this matter:—"If in turning with an ordinary-sized pelvis, one-third of the children are lost, the mortality will surely be more than doubled if its diameter be reduced more than one-fourth." Again, if the relative size of the pelvis or head be miscalculated, Dr. Churchill justly remarks, "We must then craniotomise the child, after incurring the hazard of turning, and in a most unfavourable position." But we must not further dwell upon this subject on the present occasion: we shall thus, entering our solemn protest against a proceeding so rash, so unscientific, and so dangerous, content ourselves with referring our readers to Dr. Churchill's work, to Dr. Collins's Letters, and to Dr. Radford's papers in the Provincial Journal, in all which they will find its enormity well exposed.

The nature of the instrumentality by which the placenta is detached is a question of great interest in connection with the occurrence of *post-partum* hæmorrhage. We shall therefore place

before our readers a full statement of the views of the authors on these subjects.

Dr. Miller observes:—

"In many cases of labour there can be no doubt that the pain which expels the child detaches the placenta at the same time; for it can be felt by the finger over the uterine orifice immediately after the birth of the child. Where, however, this does not take place, and the separation is a distinct and special part of labour, it will be found, I apprehend, that *tonic contraction* of the uterus is the means employed by nature to accomplish it. This is not the account usually given by writers, who speak of the return of pain (muscular contraction), after a longer or shorter interval, to separate as well as expel the placenta and membranes. From many observations, carefully made, I deem myself justified in concluding that, when the placenta is not detached by the last labour—three preceding the expulsion of the child, it is by the agency of the tonic contraction alone that the uterus dissolves the connection between itself and the placenta. I have many times introduced my fingers up to the os uteri, passing them along the cord as a conductor, immediately after the birth of the child, without being able to reach the placenta; and I have repeated the examination several times at short intervals, until the placenta could be reached in this way, and satisfactorily ascertained it to be lying loose and unattached, notwithstanding *pain* had not been complained of by the patient, although frequently asked if she felt pain. From observations like these it may be safely concluded that the placenta is detached without pain—viz., without muscular contraction of the uterus; and the only other agent that can be operative is *tonic contraction*" (p. 408).

The nature of uterine muscular action, Dr. Miller observes, is expulsive, and implies the presence of something to be expelled; "but the placenta and membranes, so long as they are attached to the inner surface of the organ, are in bonds of vital union with it, and cannot in any sense be reckoned as extraneous matters" (p. 410).

Dr. Miller's account of the manner in which the placenta and membranes are expelled is as follows:—

"The separation begins with the placenta, and commences usually about its centre, extending gradually towards its margin. While this is going on more or less blood escapes from the denuded mouth

of the uterine vessels; and, by its pressure, forms the detached portion of the placenta into a cup-like cavity for its reception. When the attachment of the margin of the placenta is broken up, the entire mass falls by its gravity, or is pushed by uterine contraction to the external orifice of the womb. "The separation of the placenta sometimes takes place differently: its margin may be detached first."

In this case, the author observes, the placenta assumes a cylindrical form, and its uterine lobulated surface is presented to the finger, attended with more or less hæmorrhage, from want of the placental cup to detain and restrain it.

On the means employed to detach the placenta, Dr. Churchill remarks:—

"The contractions which expel the child may detach partially or wholly the placenta, or it may be unaffected by them: in this state it will of course remain until the recurrence of uterine action. But cases not unfrequently occur in which the uterus remains quiescent after expelling the child, owing sometimes to the length and severity of the labour, and sometimes apparently to a peculiarity of uterine constitution,—in other words, to a cause unknown" (p. 389).

This "cause unknown," we may be permitted to suggest, is the absence of the "tonic contraction" to which Dr. Miller, we think with justice, attributes the complete expulsion of the secundines, and without the occurrence of which great risk of hæmorrhage is incurred.

Dr. Miller regards the application of a second ligature to the umbilical cord as entirely superfluous. "It is now well known that whatever bleeding may occur (from the placental portion of the cord) proceeds from the foetal vessels in the placenta, and cannot, of course, affect the mother, while by depleting the placenta it only makes its expulsion easier." Dr. Churchill still enjoins the application of the second ligature. We concur in Dr. Miller's views. This is a point, however, of no great importance practically, although it affords some indication of the scientific character of the practitioner.

Both Dr. Miller and Dr. Churchill wisely counsel the speedy removal of the placenta: its remaining in the inert uterus can only be the source of evil. But the method of its removal differs in the hands of these authorities. Thus Dr. Miller employs traction on the cord: Dr. Churchill discounts

the practice, from the risk of breaking the cord, and of producing hæmorrhage by withdrawing the placenta whilst the uterus is relaxed. For our own part, the plan and *precautions* recommended by Dr. Miller are those upon which we have ourselves always acted, and have generally found efficient in inducing its expulsion by the tonic contraction of the uterus, when the muscular contraction has not detached it, as it seldom does. The hand placed on the abdomen has always served to indicate whether the uterus be so much relaxed that hæmorrhage would follow its removal. In such cases the hæmorrhage will probably have already occurred. The introduction of the hand may become indispensable; but, as Dr. Churchill truly remarks, it is "an operation not to be lightly undertaken, as it is one by no means free from danger." We would impress this caution upon junior practitioners; at the same time we would add Dr. Miller's rule, "to deliver the placenta at the expiration of an hour from the close of the second stage." Whatever may be the cause of the morbid retention, we believe that the best practitioners, both in America and in Great Britain, agree that it is not advisable to interfere sooner, nor safe to defer the delivery of the placenta beyond that time.

In the hæmorrhage which occurs after the expulsion of the child, Dr. Miller lays great stress upon the effect of the introduction of the hand into the uterus, in exciting that organ to contraction when other and external means have failed. Dr. Miller also testifies to the good effects of cold applied externally.

Dr. Churchill regards the introduction of the hand into the uterus as "so hazardous a practice that nothing would justify it but the failure of all previous means" (p. 413). We fully agree in Dr. Churchill's opinion, which is in no degree counter to that of Dr. Miller. Among the other means which we have found of much use in post-partum hæmorrhage is the injection of cold water into the uterus. We have also found the ergot of rye a valuable aid, and cannot, therefore, concur in Dr. Miller's utter disregard of this drug. We agree in Dr. Churchill's commendation thereof, *when judiciously used*. But at the same time, we have frequently seen retained placenta and hæmorrhage

from irregular contraction of the uterus, caused, we believe, solely by the too early use of ergot.

We regret much that our space forbids our further extension of the comparison of these works. We think, however, that the points we have already touched upon may be regarded as fair indications of the character of the principles and practice of the respective teachers. If our readers should feel disposed to follow our example, and make a comparison for themselves, we are sure they will derive much instruction from the investigation. Each author has produced a work of very great merit, and such as we can confidently recommend to the study of every obstetric practitioner. Both authors have ably represented their several schools; and, as the result of our comparison, we cannot say that one is in any respect behind the other; but we may observe that Dr. Miller's work bears a feature which is possessed by most American works on midwifery,—that of partaking very largely of the literature of the French school. The authors quoted by Dr. Miller, although Burnet and Hamilton are his models, as well as by Dr. Meigs, whose works we reviewed some time since, are for the most part French. We think it only fair to claim for Dr. Churchill, as the representative, for the occasion, of British midwifery, that his work displays greater self-reliance. He trusts more to his own facts and observations in the practical conclusions at which he arrives.

Wonders displayed by the Human Body in the Endurance of Injury. From the Portfolio of DELTA; with Etchings by the Author. Pamphlet, 8vo. pp. 39. London: Renshaw. 1850.

THIS is a chapter of accidents,—marvellous accidents,—including the most extraordinary and out-of-the-way instances of such phenomena as phosphorescence, spontaneous combustion, voluntary control over the action of the heart, the endurance of pain, protracted fasting, premature sepulture, the swallowing of spoons, forks, knives, &c. &c., the endurance of most severe injuries, the reception of foreign substances, such as instruments of various kinds, within the body.

This pamphlet presents a curious collection of wonders displayed by the human body in its endurance of injury.

Corpulence, or Excess of Fat in the Human Body; its Relations to Chemistry and Physiology; its Bearings on other Diseases and the Value of Human Life; and its Indications of Treatment: with an Appendix on Emaciation. By THOMAS KING CHAMBERS, D.M., Fellow of the Royal College of Physicians, and Gulstonian Lecturer for 1850. Small 8vo. pp. 166. London: Longman and Co. 1850.

We should scarcely have thought it possible that so interesting and instructive a volume could have been composed on the subject of "Corpulency" as we have before us in Dr. Chambers's work. The author treats this state in all the relations indicated on his title-page, so very fully and ably, as to excite surprise at the variety and extent of aspects under which it may be viewed.

The following extract points out the character and limitations of the morbid condition which constitutes the disease of which he treats:—

"Obesity, or polysarcia as it is called by systematic writers, must be viewed as a true hypertrophy of the *tela adiposa*,—an increased growth, without change in chemical or anatomical characters. I am the more anxious to give this definition, in order to draw a strong line of demarcation between such a state and that degeneration of muscle and other tissues into fat, to which the labours of Professor Rokitsansky have latterly drawn such deserved attention. He designates this degeneration as a *false* hypertrophy. 'False hypertrophies,' he observes, 'are recognisable at the first glance, by the alienation of the whole habit of the organ. . . . They appear as fatty disease of the liver, as albuminous, lardaceous infiltration of the same, of the spleen, of the kidneys . . . as a change of the muscular fibrils into molecular fat, with destruction of the transverse striae, and irregular distension of their sheath.' What he calls false hypertrophy is better classed by Mr. Paget as an atrophy; for in it, while the organ is altered in shape, and sometimes also in size, the interstitial nourishment of its tissue by the substance proper to it is certainly diminished. Indeed, this last state is so entirely different from an increased accumulation of fat, that the two may be pathologically contrasted; in that, the substance of some necessary part of the body is removed, and replaced by a matter foreign to it; but in obesity, the tissues of all the members remain intact, possess all the parts requisite to execute their offices, and are only impeded in the

performance of them when the additional superimposed matter alters the shape so far as to offer a mechanical obstacle, to free action." (p. 3.)

The author carefully draws a distinction between the two kinds of fat; molecular and vesicular. He gives a minute description of the anatomical characters of the fat vesicles. The mechanical and chemical uses of fat are also related. The origin of fat, its chemical and physiological history, are treated of *in extenso*.

Dr. Chambers has fully considered the value of the weight of fat as influencing the value of life in relation to insurance, has pointed out the variations observed in different ages, seasons, &c., with the predisposing causes of obesity, its anatomical characters, the mode in which it operates injuriously, and lastly its treatment.

In the discussion of all these considerations, many topics are embraced to which we have not been able to allude.

The reverse condition, that of *Emaciation*, is considered in the Appendix, in relation to the absorption of fat in health and disease, and the chemical theories which have been advanced to account for its assimilation. The author refers in this portion of his work to the emaciation of phthisis, and the fattening properties of Cod-Liver Oil, quoting the Report of the Brompton Hospital for testimony as to the powers of the last-named remedy.

We regret that we have been able but very imperfectly to represent the contents of this book: we would strongly advise our readers to possess themselves of the work itself, which they will find amply to repay the short time it will occupy in its perusal.

Vision in Health and Disease; the Value of Glasses for its Restoration, and the Mischiefs caused by their Abuse: being the substance of Lectures delivered at the Central London Ophthalmic Hospital. By ALFRED SMEE, F.R.S. Pamphlet, pp. 64. London.

THE nature of these lectures will be apparent from the title-page above quoted. The reason for their publication is stated by Mr. Smea to be the repeated solicitations by various persons that he would publish a Treatise

on Vision, &c., and the assurance that such a treatise would be acceptable to the public. To this he "consented upon the express condition that the book should be published at the lowest possible rate." The book thus resulting, and which has now been some time before the public, is, on the whole, a very good popular exposition of vision and its morbid states. It contains much interesting information; and we consider it to be one of Mr. Smees's best productions.

Proceedings of the Medical Society of the State of Pennsylvania, at its Annual Session held in the City of Philadelphia, April 1850. Pamphlet, 8vo. pp. 55.

THE proceedings of the Society are introduced by an appeal to the body of practitioners throughout the State in behalf of the Society, and calling for an organization of local Societies in communication with the central Society.

The business of the session consisted in the passing of various resolutions having for their objects the promotion of medical science and the improvement of the *status* of the profession.

A report was presented by a committee appointed to investigate the recent prevalence of small-pox. From a table which is given it appears that variola has prevailed epidemically in America at various intervals. The following years exhibited its greatest prevalence in Philadelphia:—1808-11, 1816-17, 1823-24, 1827-28, 1833-34, 1841-42, 1845-46, 1848-49, showing periods or intervals of from two to five years. The accompanying remarks on the protective influence of the disease itself, and of vaccination, are deserving of perusal, as tending to explain the discrepancies met with in the history of vaccination.

The volume concludes with an address to the profession on the importance of the organization thereof, argued from the analogy of nature and of society in all ages. We trust that the talent and the zeal displayed in the promotion of the objects of this Society will not be exerted in vain among our Pennsylvanian brethren.

Proceedings of Societies.

MEDICAL SOCIETY OF LONDON.

Oct. 15, 1850.

DR. J. R. BENNETT, PRESIDENT.

[THE first meeting of this Society took place at the new rooms, in George Street, Hanover Square, on Saturday, the 12th instant.]

Cases of Extra Capsular Fracture of the Thigh-bone. By Mr. COULSON.

The first case occurred in a man aged 77, who caught his foot in the carpet whilst crossing a room, and fell on the trochanter-major of the left side. Considerable effusion took place in the region of the joint; the limb was shortened two inches, and slightly everted. There was great pain about the joint, and involuntary twitchings of the muscles of the limb; and, at the end of a month from the accident (Aug. 11) he died, worn out by his sufferings. On examination, the bone was found to be broken at the neck, the fracture extending obliquely from without inwards, and involving a portion of the shaft of the femur; but leaving the trochanter minor untouched. Posteriorly there was another fracture, including the trochanter major, the inter-trochanteric space, and the trochanter-minor, with a portion of the bone beyond it.

The second case was that of a woman aged 76, who, on getting out of bed in the dark, fell down and struck her left hip. The foot was shortened about two inches, and everted, and the pain was considerable in the region of the joint on pressure or motion, but the pain was not great when the part was left quiet. The patient lived three months, and died more from bed-sores than from the irritation caused by the accident. On examination, the neck of the femur, as in the preceding case, was found broken obliquely from without inwards, the fracture enclosing a portion of the shaft of the bone. Posteriorly there was a comminuted fracture of the trochanter-major and inter-trochanteric space, extending to the trochanter-minor, but not including it.

Among the points of interest connected with these accidents, Mr. Coulson observed that in both cases there was a double fracture—a fracture through the neck, extending down the shaft of the bone, and a second through the inter-trochanteric space. Mr. Smith, in his valuable work on "Fractures in the Vicinity of Joints," in

alluding to this subject, remarks, that in upwards of a hundred cases of extra-capsular fracture of the neck of the femur, which he examined, he had found, and in all without a single exception, a second fracture, traversing some portion of the inter-trochanteric space. He considers that "the neck of the femur is, in the first instance, broken by the fall on the hip, and then driven into the cancellated tissue, between the trochanters, by the weight of the body, and the prolonged action of the first shock; but, as soon as the neck of the bone is broken, the femur is rotated outwards, even before the action of the first impulse has ceased: thus, the posterior inter-trochanteric ridge being thrown forwards, is forcibly driven against the back of the neck of the femur. Two forces, therefore, combine to produce the fracture through the inter-trochanteric space, one of which consists in the impaction of the cervix into the shaft, whilst the other is found in the collision which takes place between the broken neck of the bone and the posterior inter-trochanteric ridge."

Angina Membranacea, or Diphtheritis, and its Treatment. By Dr. BENNETT.

The peculiar form of pharyngeal inflammation which has been so ably investigated and well described by Bretonneau, and to which he gave the name of diphtheritis, is a disease comparatively little known in this country. Some of our best authors make no mention of it: many practitioners have never seen it; and, though we can by no means assent to the accuracy of the views taken by Bretonneau and other French writers, as to its identity, in certain forms or complications, with the ordinary true inflammatory croup of this country, yet those only who are practically acquainted with the disease as well as with its history, as detailed by the French writers, can judge of the grounds for inferring a relationship between the two. The disease has usually appeared as an epidemic rather than as a sporadic affection; and, like most other epidemic diseases, has doubtless varied somewhat in its aspects with variations of the epidemic constitution. Hence, also, the different names which there is good reason for believing have been given to the same disease: for, whilst by some it has been confounded with, and described as croup, it has by others (and this more frequently) been designated as angina maligna, or malignant sore-throat. At all events, the disease which Bretonneau described was, previous to his investigations, considered to be characterised by extensive and malignant ulceration of the throat as its most prominent feature; and there is sufficient evidence in the writings of our

own countrymen to prove that, under the designation of croup, or some analogous term, diseases have been described which primarily were diseases of the pharynx. But the investigations of Bretonneau demonstrated that, except in the rarest cases, the formidable epidemic angina which he described was unattended by sloughing, or even ulceration, of the mucous membrane. The comparative infrequency in this country of the disease to which Bretonneau gave the name of diphtheritis (but for which angina membranacea is a preferable term) may to a certain extent account for the paucity of any very accurate or precise information respecting it as a British disease. There are not wanting, however, accurate and distinct histories of the malady in the records of British medicine, and doubtless there are many medical men who have had practical acquaintance with it. The investigations and views of Bretonneau are, indeed, sufficiently well known among us. But, unless I am mistaken, there are comparatively few who can say that they have tested, by their own observation, the accuracy of the pathological views of Bretonneau.

The author then related several cases which had fallen under his notice in the course of the present year, and concluded as follows:—The first point to which I would call attention is the epidemic character of the disease. All the cases I have mentioned, and others of which I have heard, occurred about the same period of the year. With respect to the question of contagion, without venturing to express any decided opinion, I may observe that the first and the last cases mentioned occurred in families where there were other children, who were not separated: some of them took the disease. The French writers are pretty unanimous in attributing a contagious character to the disease. With the exception of the first case, all the children were apparently in good health when attacked; in all, the disease was of an adynamic type, languor and depression of system from the first characterizing all the cases. In all, the throat affection had attained a very serious and formidable character before there was either much difficulty of swallowing or external swelling, and before there was any difficulty of breathing, or other symptom referable to the larynx or lungs. There was nothing like preceding catarrh in any of the cases. Stomatitis prevailed at the same time, and my own observation would lead me to concur with most of the French pathologists in assigning a close relationship between this affection and diphtheritis, if not an absolute identity. But it may naturally be asked, does not the existence of

ulceration in the one case, and its absence in the other, indicate an important pathological distinction? To this it may be replied, that stomatitis is essentially characterized by the same fibrinous exudation, and that, although ulceration does undoubtedly frequently attend it, the great similarity of appearance in the two conditions often leads to the supposition that there is more ulceration than actually exists in ordinary cases of stomatitis. I have frequently had occasion to observe, that on the separation of the ash-coloured patches, around which the mucous membrane was red and tumid, so as to give them the depressed form, as well as colour, of ulcers, the mucous membrane was still entire. It must, however, be admitted that, whilst it is only rarely that ulceration attends the disease, when confined to the fauces and soft palate, as a general rule, when assuming the form of stomatitis, there is more or less of ulceration associated with the fibrinous exudations. This may perhaps depend on the difference of situation, the inflamed membrane in the one case being more exposed to mechanical and other sources of irritation. As to the general or constitutional symptoms, there is the closest resemblance; and I believe that the same general plan of treatment will be found applicable to both sets of cases. The fact, also, of the two affections having very generally been found to prevail at the same time, renders it highly probable that they are the result of the same general cause. This question of relationship with the more common affection (in this country at least) of stomatitis is, I think, important as regards treatment. For many years I have now been in the habit of prescribing the *chlorate of potash* in the stomatitis of children, and with such marked advantage that I cannot doubt its exerting a peculiar and specific influence. Of its great superiority over the more ordinary plan of giving mercurial alteratives I have myself no doubt. Mercury has appeared to me to be of very questionable utility in most cases, and in others to be positively prejudicial. The author then proceeds to say that he regards the type of the disease as essentially adynamic, and that the treatment must always have regard to this fact. With respect to treatment, he lays great stress on the value of the application of the solution of nitrate of silver to the affected parts, and cautions the practitioner to be constantly on his guard, and not to be taken by surprise by the sudden invasion of croupy symptoms. The general treatment must be tonic and supporting.

I have been led to look on the disease as the result of a specific epidemic influence, operating on the system through the blood,

characterized by an adynamic type, and calling for special treatment; and that, however much the general symptoms may be modified by the occurrence of laryngeal complication, the secondary croup which then sets in is a distinct affection from the common sporadic croup of this country, and not amenable to the same treatment, whether in the simple or complicated forms, is of the utmost importance; that the more common form of stomatitis is essentially the same affection as that which attacks the pharynx. As, however, the term stomatitis, like croup, has been applied in the most confused way to various totally distinct diseases, I ought to say that, in using this term, I restrict its application to the buccal affection chiefly seen in children, and characterized by the effusion of fibrine and spreading superficial inflammation, and excluding, on the one hand, the more trivial cases of aphthae and infantile thrush, and, on the other, the still more formidable cancrum oris, or sloughing inflammation of the cheek. I have made no allusion to diphtheritis, as affecting the adult, because I have never seen a well marked instance; but I have reason to believe that several cases occurred last summer; and the well-known paper of Louis, on croup in the adult, describes, in fact, cases of angina membranacea, complicated by extension of the disease to the larynx.

ACADEMY OF MEDICINE, PARIS.

Vaccination—its protective power depending on the manner of its performance.

M. DELAFRAYSSE stated in a note, that he had arrived at certain conclusions as the result of his investigations into the causes of the failure in the protective power of vaccination against small-pox. His experience had convinced him that vaccination is an infallible preventive where the vesicles are sufficiently numerous to produce a degree of febrile reaction, and that its failure is to be attributed to the insufficient development of this febrile reaction, or to its non-occurrence. He proposes that, instead of the four or five punctures usually made on the arm, from twenty to thirty should be practised on different parts of the body. In confirmation of his views, M. Delafraysse states that he has with impunity exposed all the children that he has so vaccinated to the greatest risk of contracting small-pox.

Functions of the Bulb of the Urethra.

M. GUÉRIN (of Vannes) read a memoir on this subject, in which he stated that, from his observations and experiments, he had arrived at the conclusion that the bulb must be regarded as an appendix to the canal of the urethra, its function being to assist in the expulsion of the last drops of urine by the afflux of blood from behind, propelled by the contraction of the bulbocavernous muscle, thereby producing a modified state of congestion of the cavernous and spongy structures of the penis and urethra.

This discovery M. Guérin considers sufficient to explain the turgidity of the penis in cases where ineffectual efforts at urination are made; also the fact of the retention of a few drops of urine in the urethra in cases of chronic inflammatory stricture, the altered mucous membrane preventing the due propulsion of the blood towards the gland during the contraction of the muscle.

ACADEMY OF SCIENCES, PARIS.

Diseases of Persons employed in the Manufacture of Quinine.

M. CHEVALLIER stated the following results of his investigations on this subject:—

1. The workmen are attacked by a cutaneous disease which compels them to suspend their labours for fifteen days, a month, or more.
 2. Some workmen are compelled entirely to abandon their occupation.
 3. Herr Zimmer, of Frankfort, has observed that the workmen employed in the pulverisation of quinine have been subject to a peculiar febrile attack, to which they give the name of "quinine fever" (*china fieber*). This malady is so painful that many workmen quit their employment on that account.
 4. This disease has not been noticed in France.
 5. The proper prophylactic measures are not known.
 6. The cutaneous disease is found not only to attack those actually engaged in the manufacture of quinine, but to extend also to those exposed to the emanations.
 7. It attacks the temperate equally with the intemperate.
 8. Its predisposing causes are unknown.
- M. Chevallier suggests as precautions, free ventilation and the avoidance of contact with the decoctions, &c.

Correspondence.

THE MEDICAL PROFESSION AND ASSURANCE OFFICES.

SIR,—I have a suggestion to offer to my brethren, touching upon life-assurance certificates, founded on the following fact:—

Some time since I received a printed form, signed by a patient of mine, requesting me to answer certain questions respecting his life to the Standard Assurance Office. The paper of course came from the Office, the whole of it being filled up by the agent in this place, whose handwriting I knew.

I replied to the agent, that on his assurance that I should be paid a fee I would afford all the information in my power, but not otherwise. Upon this that gentleman called on me, and endeavoured to convince me that it was for my patient's benefit, and not for the benefit of the Office, that the information was sought, and that, as his medical attendant, I was bound to give it. I replied, that when my patient employed me he always paid me, and that now, far from wishing to employ me, he was willing to pay his insurance bonus without troubling me, and thus to fulfil his part of the contract; and that, as the Office, for their own protection, applied to me, by the Office I would be paid, or else withhold my information, and that I would not be paid by the patient if he wished it.

Before writing to the agent I saw my patient, and explained to him how matters stood. He at once, as a man of business, saw the justice of my demand on the Office, and promised to back me in it. I further told him that the office in which my own life was assured would pay me, and that it was an office of equal respectability with the Standard.

I must further say that, in going to call on my patient on the occasion mentioned, I met the principal clerk of the attorney (a highly respectable practitioner), who is the agent here of my office. I said to him, "Mr. —, does your office pay the medical attendant of the persons assuring?" He replied, "We pay our own referee." "But do you pay the medical attendant of the assurer?"—"No!" "Oh, well, then, I must recommend my patients to assure in an office that does, for I am determined to fight this battle with the assurance offices." He replied, "Well, Mr. H., we can arrange that." I told him how I was placed, and that if the Standard refused my demand I would bring my patient to their office. To cut a long story short, after some little delay the agent of the Standard called and said they would pay me my fee, which they

did; and, after all was settled, the agent said that they should be glad to act in the same way again if I would recommend their office.

Thus you see that the best offices will pay when "*proper pressure*" is put on them; and that the *profession have themselves to blame if they do not obtain their just demands*. I am also, from pretty considerable experience, justified in saying that the public generally are fully prepared to back the just demands of their professional advisers when the matter is explained to them.

I was much pleased to see the list you lately published of the offices which pay; and I think much good would be done if you and your cotemporaries were to publish occasionally—say in the first number of every quarter—a list of the offices which do recognise the claims of the profession. We should then be able at once, at any time, to recommend our patients to these offices when called on to do so, and at the same time a salutary stimulus would be given to the non-paying offices. My suggestion, then, is, in all cases of assurance stand firm, and you will obtain your demand.—Your obedient servant,

J. H. HOUGHTON.

Dudley, Oct. 18, 1830.

N.B. A brother practitioner has informed me that he has obtained a like result from the same office by the same proceedings.

Medical Intelligence.

THE CHOLERA AT ALEXANDRIA.

INTELLIGENCE from Alexandria, dated October 9th, states that the cholera, after having entirely disappeared from the country for many days, had again broken out on the 8th instant, and four cases were reported. It is attributed, however, to the excessively oppressive weather, and the first shower of rain will, it is expected, restore the town to its usual good health. No rain has fallen there since March, and the first shower is anxiously looked for to cool the air.

THE CHOLERA AT HAVANNAH.

PRIVATE letters from Havannah dated the 22d ult. state that the cholera had broken out on the south side of the island, where it had not appeared before, and was attended with considerable mortality amongst the slave population. It had also made its appearance in the centre of Cuba, where the negro population was numerous.

EFFECT OF HEAT IN EXPANDING METALS.

THE Britannia tubular bridge has afforded by its great length some curious results in reference to the expansion of iron by increase of temperature. An increase of 26°, namely from 32° to 58°, gives an increase of length of *three and a quarter inches* in the whole bridge, which at 32° is 1510 feet one inch and a half long. The expansion is thus one-eighth of an inch for each degree, or 1-14,500th part of the whole length. The daily expansion and contraction of the tube varies from half an inch to three inches, or 1-14,500th part of the whole length. When the sun is shining on one side and the other side is cool, the heated portions expand, and thereby warp or bend the tube towards the heated side, the motion being as much as two and a-half inches vertically, and two and a half inches laterally. Clouds passing before the sun affect the rate of expansion by rapid cooling, and singular curves of heat are thus described by self-acting clock work. Even in the dullest and most rainy weather the tube rises slightly, showing that heat as well as light is radiated through the clouds. On very hot sunny days the lateral motion has been as much as *three inches*, which is considerable, when it is remembered that the deflection of the tube produced by a heavy train is only three-tenths of an inch, and that a violent gale does not bend it more than a *quarter* of an inch.

A LUNATIC BALL AT ST. LUKE'S HOSPITAL.

ON Friday last, the 18th inst., being St. Luke's day, the entertainment of dancing and singing was afforded to a large number of the unhappy objects of this charity under circumstances of peculiar interest. It was the first occasion of this kind which had taken place at St. Luke's, and from the successful issue of the undertaking it may be expected to be repeated. It appears that under the judicious management of the resident officers, acting with the sanction of the house committee, and upon the suggestion of the physicians, between 60 and 70 of the patients, men and women, were assembled at 6 o'clock in the evening in the great hall in the centre of the building, and music being provided, they were quickly arranged in their places for an old English country dance. This, with appropriate changes, was kept up with great spirit until 9 o'clock, when all retired peaceably and cheerfully to their respective apartments. The officers of the establishment, with such nurses and attendants as could be spared from the galleries, joined merrily in the dance. By this means the confidence of the patients was secured, and they showed themselves grateful for the enjoyment afforded them, by entering into the amusement

without levity or boisterous conduct of any kind. The vigilant eye of the matron rested anxiously upon the women, many of whom had been but recently admitted in an apparently hopeless state of lunacy, and the excitement was upon the whole the more important in the case of this hospital, as it is the practice to receive within its walls the most violent cases of acute mania, and to retain them only until cured; or until, after a twelvemonth's trial, the disease appears beyond the relief of human skill. There are at present 196 patients in the hospital—91 men and 105 women. The average of cures during the last year was 60½ per cent, being a considerable improvement upon former years.

REMUNERATING AND NON-REMUNERATING INSURANCE OFFICES.

WE had intended to publish a list of the Metropolitan Insurance Offices which do not remunerate Medical Referees for their certificates, but we find the number of non-remunerating offices so large, that we have no room for the list.

The metropolitan offices will be found at page 89 of the British Almanack, for 1850. Out of a list of 125, there are only 32 which profess to pay medical referees for their certificates. The 93 which do not pay, but (when they can get them) procure medical certificates and act upon them without a fee, comprise, unfortunately, the oldest, largest, and most influential offices, such as the Sun, the Book, Eagle, Atlas, and the London Assurance Corporations. Medical men, however, have one clear and distinct rule to follow—i. e., to sign no certificate without a fee, and to inform their patients that this rule has been now generally adopted by the profession.

UNIVERSITY OF CAMBRIDGE. LECTURES ON COMPARATIVE ANATOMY AND PHYSIOLOGY.

THE Professor of Anatomy commenced a course of lectures on comparative anatomy and physiology in the Anatomical School on Wednesday, October 28, at one o'clock. The lectures, to be delivered on Mondays, Wednesdays, and Fridays, at one o'clock, will be twenty-four for the present term. The course will commence with a review, illustrated by diagrams and preparations, of the anatomy and physiology of man, as the term of comparison, and will then proceed to the anatomy and physiology of animals, according to the ascending series. Gentlemen who purpose to attend these lectures with the intention of obtaining the Professor's certificate, which, by grace of the Senate (October 31, 1848), is now required, under certain conditions, for the degrees of B.A., honorary M.A., and B.C.L., must be provided with the professorial

lecture ticket, for which they are requested to apply to the registrar, or to their college tutor.

HARVEIAN SOCIETY.

THE following gentlemen have been elected office-bearers for the present session.

Presidents.—Dr. Chowne, and H. Burford Norman, Esq., F.R.C.S.

Council.—Dr. Nathaniel Grant; Dr. Joseph Ridge; Edgar Barker, Esq., F.R.C.S.

Dr. Stroud, Treasurer, 20, Great Coram Street, Brunswick Square; and Dr. R. Hutchinson Powell, Honorary Secretary, 21, Edward Street, Portman Square, *ex officio* members of Council.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 17th October, 1850:—Henry Vincent Garman, Bow Road—George Peat Dunn, Ledbury, Herefordshire—William Hewitt, Reading, Berks—Joshua Hartley, Malton, Yorkshire—Chas. Caulfield Moore, Brimsfield, Gloucestershire.

OBITUARY.

On the 14th inst., aged 58, Mr. William Bates, Surgeon, of George Street, Blackfriars Road.

DR. FOUQUIER.

THE Faculty of Medicine of Paris has just suffered a loss, by the death of Dr. Fouquier, Professor of Clinical Medicine to the Faculty. He had reached the age of seventy-four, and was universally esteemed and respected. Dr. Fouquier had been the favourite physician of Louis Philippe for a considerable period, and commanded a very large practice. It is generally allowed that he fully deserved the distinguished rank he held in the profession, and he was particularly beloved by his patients. He has not left any medical works of note: a few therapeutical essays, and a translation of Brown's book, as well as a share in one of Celsus's, comprise the whole of his literary remains.

Selections from Journals.

ON THE CAUSES OF DEATH IN NEW-BORN INFANTS.

DR. CASPER, in his series of "Inspections of the Dead for Judicial Purposes," a former portion of which will be found at p. 218 of the eighth volume of the present series of the MEDICAL GAZETTE, and of which a succeeding portion appeared

in Casper's *Wochenschrift*, Nos. 47 and 48, 1849;—has recently given the results of forty-six post-mortem examinations made for judicial purposes on the bodies of infants.

These notices are prefaced by a few preliminary observations in reference, 1st, to the indications afforded as to the maturity of a fetus: 2nd, on the hydrostatic test; 3rd, on stelectasis.

1st. Dr. Casper states that from the observations which he has made, he would lay down a rule, which he is not aware has been stated before, that the mass of the body of fetuses and new-born children furnishes a surer indication of the degree of maturity, than does their absolute weight.

2nd. With reference to the hydrostatic test, Dr. Casper combats Henke's objections, which, he considers, have only tended to introduce uncertainty on this part of the subject. The hydrostatic test Dr. Casper considers as affording in every degree trustworthy conclusions, if performed by careful and competent hands. With regard to the objection that emphysema of the lungs would cause them to float, Dr. Casper fairly inquires whether it has ever been met with in new-born infants. In answer, also, to the statement that artificial inflation of the lungs might prove a source of fallacy, Dr. Casper also asks, Whether a mother anxious to conceal a birth would have recourse to the means of resuscitation? and doubts that this mode, which requires an anatomical and physiological education, would be known to, or could be practised by, a woman under the circumstances. Emphysema from putrefaction Dr. Casper excludes from all medico-legal considerations, by the fact that the lungs are among the last to undergo putrefaction, or that, when it has occurred, it is so evident that no mistake can occur. Dr. Casper mentions a case in which the heart being putrid, the lungs nevertheless sank.

3rd. Dr. Casper considers that pneumonia has often been mistaken for the so-called stelectasis, and gives a case in illustration, in which pneumonia was found in the lungs of a child eight days old, and those organs presented all the characters of stelectasis.

The present series of inspections illustrates chiefly the value of the hydrostatic test, and its application where death in new-born infants was shown to have occurred from apoplexy, pneumonia, &c.

Dr. Casper then proceeds with the description of his cases.

A Case in which Death occurred to an Infant from falling on its Head in the act of Birth.

This case possessed a twofold interest.

An unmarried female having arrived at the full period of her gestation, attended her master to market on Christmas-eve, and carrying a heavy basket, was unexpectedly taken in labour. The child, she said, was suddenly expelled when she had only felt the pains for half an hour, and it fell on its head on the foot-path. The umbilical cord was in this way torn asunder, and its ruptured extremities confirmed her story. The mother declared that she then fainted, and on coming to herself found the child lying dead beside her.

The hydrostatic test, and the autopsy, proved that the child had lived, and had died of effusion of blood within the cranium: about a drachm of blood was found extravasated at the base of the brain.

A deficiency in the ossification of the right parietal bone was found, in which was a portion, the size of a half florin, thin and transparent; and this presented an indented fissure one line in width. This was attributed by a physician who was present to the fall, or some other force applied at the part: but Dr. Casper points out that there was no corresponding sugillation, besides that the fissure itself, and the thinned bone around it, presented no appearance of injury.

It was considered that the child was born at the full time; that it had died of extravasation of blood on the brain; and that this extravasation was attributable to the accident attendant on its birth.

Apoplexy without Evident Cause.

A woman was delivered in a state of unconsciousness: on coming to herself, she found the child lying dead between her thighs. She divided the cord with a pair of scissors. The state of the cord bore out her assertion. Apoplectic extravasation was found within the cranium. But in such cases the statements of the accused must be received with much caution; for although it is admitted that a woman may give birth to a child under the circumstances indicated, this may be alleged to hide crime or carelessness.

Death from Pneumonia.

An infant, four days old, died without having manifested any signs of, or without any apparent cause of the inflammation. Red hepatization was found in one portion; this sank in water. The remainder of the lung floated.

Anencephalus.

The cerebellum hung in a bag of dura mater in the situation of the occipital bone. A portion of cerebral substance was contained in an abnormal cavity formed by an expansion of the two first vertebrae. The imperfect head was placed on the shoulders,

The integuments of the chin were united to those of the breast. Spina bifida of the entire vertebral canal existed.

Infanticide?

— K. was charged with having concealed the birth of a child on a certain day. This she denied when questioned by an experienced midwife, notwithstanding the discovery of a fresh afterbirth on a board in her room, and behind her bed, rolled up in an apron, and smeared with blood and dirt, the body of a child, warm, but lifeless. It was clear that she had given birth to the child at the foot of the bed, where a quantity of blood was found. A pair of scissors, smeared with blood, were found on the window seat, and under the bed a bloody cotton cord.

The girl afterwards declared that she had become insensible from the severity of the pains, and that she was delivered of the child in that state. With regard to the division of the umbilical cord she professed utter ignorance.

On examining the body of the infant, there was found a mark round the neck about two lines in width, of a lighter colour than the surrounding integuments. Besides this, the important points which were observed were congestion of the liver, emptiness of the bladder, fulness of the large intestines, the abdominal veins loaded with dark red fluid blood. The lungs, without the heart, weighed about two ounces and a half; they floated readily in water; when cut, crepitated, and on pressure yielded a sanguineous frothy mucus. The cavities on the right side of the heart were empty; on the left side they were filled with blood. The cranial bones were loaded with blood. The membranes and vessels of the brain were also greatly congested. Thence it was concluded that the child was born alive at the full time, and had died of apoplexy, and that the cotton cord was tied round its neck after death. The diagnostic marks of strangulation were wanting.

Two other cases afforded evidence in reference to the value of the hydrostatic test. The first was a female infant found in the water. The body was already partially decomposed. The lungs were of a dark brown colour, but sank in water.

In the second, a male child found in water, the body was putrefied and emphysematous. The diaphragm rose to the fourth ribs; the pericardium was not covered by the lungs, which were of a dark brown colour, and of the consistence of liver, and sank readily in water. In both cases it was concluded that the children had not been born alive.

A female new-born infant was found

in the water. It was mature, had lived, was apoplectic, and had not died by suffocation. Other circumstances attending the finding of the bodies confirmed this opinion.

The body of a male infant was found on a dunghill. The rats had partly devoured it, and only a portion of lung remained. From this it was possible to determine that the child had lived. The lung was crepitant, and floated. The brain showed the appearance of apoplexy. The abdomen had been pierced by a dung fork.

The body of an infant was found in the street. It had never breathed. The bladder was empty. What is the value of the latter circumstance, Dr. Casper inquires?

A child was delivered footling; the head was arrested in the pelvis. When assistance arrived the child was already dead. The hydrostatic test, showed it to have been still-born. Dissection discovered, upwards, of an ounce of extravasated blood at the base of the brain.

The body of a female foetus was found in the water. The head and neck severed from the trunk. The body and limbs presented marks of immaturity. From the mutilation to which the body had been subjected it could not be determined whether the child had been born alive.

Two other cases showed early decomposition in the lungs. One, a female child that must have lived, was found in the water, and had died of apoplexy. There were no signs of suffocation. The tongue protruded beyond the teeth; but Dr. Casper has so often found this under other circumstances than suffocation, that he does not regard it as conclusive. In the other also there was every sign that the child had lived. In both putrefaction was but little advanced, but the lungs presented vesicles on their surfaces.—*Casper's Wochenschrift.* x

MECHANICAL OBSTRUCTION IN THE COLON OF RATHER A SINGULAR NATURE. BY DR. GRIEBS, OF BERKS COUNTY, PENNSYLVANIA.

In July 1833, I was called, two miles from my home, to see R. L., a little girl about eight years of age. She had been sick several days, and under family treatment. I found her suffering severely from pain in her abdomen, frequent efforts to vomit, and a good deal of fever. Her bowels had not been moved for several days. I administered an enema, used means to appease her stomach and to subdue pain and fever. Afterwards I gave her several doses of calomel, but when I followed it up with other purgatives, the vomiting and pain returned. I used frequent mild enemata. At first some little faeces came, but soon nothing but the injection. Upon close examination of the abdomen, and from other attending

signs, I felt convinced that there was mechanical obstruction, which the peristaltic action of the bowels could not overcome. I accordingly threw into her bowels, at last, three quarts of warm water, with a little soap, in a continued but gentle stream, by means of Maw's stomach-pump; she screamed out that we were "bursting her." Immediately on evacuating her bowels she passed large masses of dry or hard feces, in which were entangled nine large worms. I then hoped that the obstruction was overcome, and gave a few small doses of cathartic medicine to be taken till next day: but, on my visit, finding the medicine had no effect, I repeated the enema, in the same quantity, which brought away again a mass of hard feces and seven large worms. After this I had no difficulty with the case, except that she was slightly paralytic in her left leg. I have not seen her for many years; but have lately heard she is married, and has several children; also that she has since had disease of the hip-joint, and is quite lame. I think that it is not out of place here to mention a circumstance in another case of obstinate constipation. After being completely foiled in all my efforts, I determined to use tobacco injections, and upon due reflection I concluded that the smoke might suit best. I accordingly put a lighted cigar into the lateral tube of Maw's stomach-pump, and found it, thus prepared, the very best apparatus to generate and apply the smoke that could be possibly imagined. It had the desired effect.—*American Journal of the Medical Sciences*, July 1850.

CLINICAL LECTURE

ON

A CASE OF DISEASE OF THE
BRAIN,

(Delivered at King's College Hospital),

By R. B. TODD, M.D. F.R.S.

Physician to the Hospital.

(Reported by H. H. SALTER, B.A., Dem. Anat.
K.C.L.)

LECTURE XII.

I PROPOSE to call your attention, gentlemen, to two cases of brain disease that have recently terminated fatally in the hospital, which fatal termination gives us an opportunity of ascertaining positively what were the diseased conditions before death. A fatal termination to cases of this kind, although casting opprobrium on our art, yet affords us this consolation, that the post-mortem inspection clears away that amount of uncertainty which overhangs most cases of brain disease in consequence of the various complicating sympathies that accompany disease of the central organ of the nervous system. In many cases of cerebral affection, while it is sufficiently easy to determine the nature of the disease, it is very difficult to decide upon its locality. It is only, therefore, by a careful observation of cases during life, and an unprejudiced comparison of the post-mortem changes with the symptoms, that we can arrive at accurate conclusions respecting the precise value of certain symptoms, or the exact interpretation of them. A clot in one hemisphere of the brain, encroaching more or less upon the corpus striatum, will produce symptoms exactly the same as those of a similar clot deep in the substance of the corresponding cerebellar hemisphere; and it is only by the observation and careful collation of numerous cases, made complete by their post-mortem examinations, that we can expect to arrive at such conclusions as may hereafter enable us to distinguish a paralyzing clot situated in the cerebrum from a similar one situated in the cerebellum. It is curious that in heart disease the main difficulty is not as to the situation of the lesion, but as to its precise nature. We can easily enough tell whether this or that valve is diseased, or this or that ventricle dilated; but we cannot always be so exact as regards the precise nature of the lesion. On the

whole, however, we have attained in heart cases a certainty of diagnosis far exceeding that in brain diseases. This we owe to post-mortem investigation, and, perhaps, also to a more intimate knowledge of the mechanism of the organ. In a large majority of heart cases, then, we find that post-mortem examinations are *corroborative*; but in brain cases they often give us the only clear information—we possess, certainly as regards the site of the lesion—and sometimes entirely contradict our anticipations.

The first case, that of William Ware (vol. xxvi.), a ploughman from Kent, who has been in the hospital some time. He unfortunately caught erysipelas, and died of it; and it is owing to that circumstance that we have been able to see what were the causes of his symptoms. He was 30 years of age, and of temperate habits. About fifteen weeks before his admission, he was suddenly seized with paralysis of the right side of his body and face. He does not seem to have lost his consciousness at first, but awoke out of his sleep in a state of paralysis. After this, according to his own account, he lost his consciousness, and continued in that state for three weeks; but it is not probable that this unconscious condition was complete coma, as three weeks' coma is very unusual. He was probably in a heavy sort of stupor, unable, as he says, to speak distinctly, or to comprehend perfectly what was said to him, or to feed himself, and deprived totally of the power of the right side.

It is always important to see what state the patient was in before the attack: in most cases you will find something wrong. Our patient complained of a numbness of the extremities of the affected side three or four days before the attack, no doubt dependent on some morbid change going on in the brain. After the recovery of his consciousness, he continued for three weeks in a state of complete paralysis: he used to gape very much, and frequently cried in a childish manner, as persons thus afflicted are very apt to do. At the end of the three weeks he began to recover the palsy, the leg first regaining power, then the arm; but as they had been stationary for some time, he was sent up to town.

On admission, our patient exhibited the following symptoms:—There was hemiplegic paralysis of the right side, no longer, however, complete; for he could use the leg very well, and the arm slightly. He could elevate the arm to a right angle with the trunk, and bend the elbow-joint and flex the fingers so as to grasp feebly. In protruding the tongue it deviated, as is usual, to the paralysed side; but he could move it from side to side. The face was

still slightly distorted, the cheek hanging on the right side: none of this distortion, however, was due to paralysis of the facial nerve; for all the movements of the superficial muscles were perfect: he could wink, and frown, and whistle; and when he laughed, the distortion of his face was not nearly so great as you ordinarily find it when the portio dura nerve is affected. The facial palsy was due to paralysis of the buccal nerve of the fifth pair affecting the buccinator muscle. The sensibility of the affected side was but slightly impaired. The muscles of the palsied limbs were as usual somewhat wasted: they were, however, evidently gradually recovering their state of tone, and they were free from rigidity. Galvanism had been used several times, more experimentally than curatively, and he was encouraged to take as much exercise as he could without fatigue. With the view of reducing any inflammatory process which might be going on at the seat of cerebral lesion, we gave him mercury; and while he was in a state of salivation he was exposed to the contagion of erysipelas, and was seized with that disease in a very severe form, and died.

The symptoms justify a diagnosis with regard to locality. As the paralysis was very complete, and as the motor power only was affected, it seemed in the highest degree probable that the lesion of the brain was situated in some part which exercises an important influence on voluntary motion. Now there are the best reasons for believing that no part is so intimately connected with this function as the corpus striatum. In a case, then, in which the paralysis of motion is complete, without there being any considerable paralysis of sensation, the lesion would most probably be seated in the corpus striatum, or in that part of the hemisphere which is most intimately connected with it; and of the two corpora striata we would fix on that of the left side, since the paralysis is shown on the opposite side to that in which the cerebral disease exists; and here the paralysis was on the right side.

Taking, then, this *locality* as granted, what was the nature of the disease? It might either be occasioned by a clot of blood from a sudden rupture of a blood-vessel or apoplexy, or a more slow disease, which, however, was of such a nature as to be capable of producing sudden paralysis. The suddenness of the attack, and the succeeding loss of consciousness, favour the former supposition. But it is wrong to suppose that apoplexy can alone produce this sudden paralysis (by apoplexy I mean the rupture of a blood-vessel, and the consequent escape of blood into the brain)—there may be other causes. A portion of

the brain may be undergoing a gradual process of softening for some time, and yet its continuity may be preserved, and its constitution may not be so altered as to prevent its carrying on its function as a conductor—in an impaired way, perhaps, but not sufficiently so to call attention to it. Suddenly, from some temporary stress, perhaps, put upon the parts, the fibres give way, and all power of voluntary motion is lost, as suddenly as the galvanic current ceases on breaking the circuit. This is one cause of paralysis in cases where there is no apoplexy.

But it is very seldom that such a lesion exists alone. It is, however, very frequently—I incline, indeed, to believe almost always—the precursor of apoplexy; and therefore we frequently find in these patches of white softening one or more clots of blood of various sizes. The artery or arteries leading to the part are diseased; that portion of the brain fails in its nutrition; it passes into the state of white softening; and the minute vessels, losing the support which they must receive from the firm brain-texture, and being themselves perhaps more or less diseased, give way, and allow the blood to escape into the tissue of the brain.

There is another way in which paralysis may take place—viz., by an inflammatory state of the brain-substance, which produces softening, although of a different kind to that which I have just described, in which there may or may not be rupture of fibres; but there may be deposit as the result of the inflammation, which, by its pressure, may interfere with the conducting power of the fibres.

Now I have mentioned the opposite conditions of *white* and *red* softening. These are apt to come on under opposite circumstances. *White* softening may be caused by anything that diminishes or cuts off the supply of blood to the head. In some cases, in which the carotid artery has been tied for aneurism, and the supply of blood to the brain on that side thus stopped, the patient may go on very well for a short time, and there may be no impairment of function; but during that time the process of softening has been gradually going on on that side of the brain which is supplied by that carotid; and in a day or two the softened fibres cease to maintain their continuity, and give way, and paralysis ensues.

Some years ago I attended, along with my friend Mr. Street, of Norwood, a very remarkable case of this sort. The supply of blood had been cut off by a dissecting aneurism, which had plugged up the common carotid artery on the right side, and paralysis of the left side of the body took

place. We were much puzzled to account for the paralysis till after death, when the post-mortem examination cleared it up. The account of this case was published in one of the volumes of the *Medico-Chirurgical Transactions*.

There is abundant evidence to show that under ordinary circumstances white softening is *atrophic*—i. e., dependent on imperfect nourishment of the brain, and non-inflammatory. But it may exist on the confines of genuine inflammation, the nutrient fluid being diverted from it to the inflamed portion, or it may exist around an effusion of liquid in the ventricles, that effusion being possibly inflammatory in its nature.

The second sort, the *red softening*, is inflammatory. I show you here a very good representation of it, which was made from a case of mine some time since. The portion of the brain affected was of considerable extent, there was paralysis, of course, on the opposite side, there was a stupid, comatose condition, not complete, vomas, and loss of sensibility, which continued till the patient died. But the paralysis came on gradually, and not till after these comatose symptoms had existed some time.

Now of these two conditions I think we may very justly attribute the symptoms in our patient Ware's case to a white softening, followed by a rupture of bloodvessels, and an effusion of blood.

The numbness, which he described as having occurred before the paralysis, indicated that morbid changes were slowly creeping on, and after a time rupture of the bloodvessels, and disruption of fibres, took place, when followed the paralysis and the three weeks' stupor. The former being very complete, denoted a very complete solution of continuity on some part of the centre of volition; the sudden stupor implied that pressure existed within the cranium, but only to a moderate extent, for a large effusion, capable of producing such a complete paralysis, would undoubtedly have caused profound coma.

This, I say, seems the *most probable* train of morbid processes, at the commencement of the case; but we cannot speak on this subject with great certainty, for we cannot fully depend on the accuracy of the patient's history of himself. It tallies, however, very well with what we observed of his subsequent history, and of the post-mortem examination.

A train of phenomena, however, very similar, but differing as regards the *sudden* supervention of the paralytic state, might have occurred, when the primary lesion was of the inflammatory kind.

Upon examination of the brain after

death, it was found that a considerable portion of the corpus striatum of the left side was completely destroyed and excavated, and that the cavity was filled with a creamy fluid, having somewhat the appearance of pus: the anterior and inner part of the corpus striatum was healthy, but the whole of the posterior and outer part was thus disorganized: a few bands of fibres, easily broken down, passed from one side of the cavity to the other. The creamy matter contained in the cavity was found on microscopical examination to contain great numbers of large cells, containing oily matter in large globules, and also in a state of extremely minute subdivision. These curious organic globules might suggest the idea, that some active reparative process was going on during life. What their precise signification is, I do not pretend to determine; but I think I may affirm that they are characteristic of a state of white softening, as I have found them in other cases, in which no doubt could exist of the atrophic nature of the lesion.

It seems almost certain, then, that this excavation of a portion of the corpus striatum must have been due to a white softening, followed by an effusion of blood, and which was the immediate cause of the breaking down of the fibres, and of the pressure which gave rise to the paralysis. No traces of blood remained on the diseased part, as no doubt there had been ample time for the disintegration of its particles, and for its absorption.

At first the paralysis was very complete, but afterwards the patient recovered a certain amount of power, especially in the lower extremities. If the paralysis had been accompanied with rigidity, I should have been led to the conclusion that the cerebral lesion was of an irritating nature. This rigid state of the paralysed limb (*when it comes on at the same time as, or very soon after, the paralysis*) is generally seen when some superficial part is affected, as the meninges, or the surface of the brain, or when there is a growth from the skull, or a tumor in the hemispheres, in some cases of inflammatory softening, or in some conditions keeping up a constant irritation; but when there is simple rupture of the fibres of a deep-seated part of the brain, as the corpus striatum, with or without pressure, there is no irritation: the paralysed muscles are quite lax.

There was no appearance whatever of rigidity in the muscles of the paralysed limbs. Now this is just the sort of paralysis (accompanied as it was by comatose symptoms) which would arise from a solution of continuity of fibres in the first instance, and from compression. A portion of the corpus striatum is destroyed, and the

healthy part is compressed by the effused blood. On the absorption of the latter a certain amount of power had returned in the limbs; and it depended on the possibility of repairing the broken-down portion, whether a complete restoration would take place. That parts so much diseased would have ever been completely repaired seems extremely unlikely for two reasons—first, because the arteries of the part did not seem in a perfectly healthy condition; and, secondly, because of the well-known tardiness of all reparative processes in the brain, where actual solution of continuity has taken place.

You remember that on several occasions we passed the galvanic current through the paralytic and the sound limbs in this case. This was done, as I explained to you at the time, for the purpose of ascertaining whether any irritant disease existed within the cranium at the seat of the paralyzing lesion.

If, on passing the galvanic current, you produce less contraction in the paralysed than in the sound side, then you may judge the cause to be of a *depressing* kind: if, on the other hand, the contractions in the diseased limb are the strongest, then you may conclude that the condition of the centre which causes the paralysis is *irritative*. But then you may bear in mind that that irritation is not always inflammatory.

The most important points in this case may be thus summed up:—

First, through some diseased state of the assimilative process, the arteries of the brain become diseased, and an insidious gradual process of softening takes place; rupture of one or more blood-vessels follows upon this, with solution of continuity of fibres, and compression of the neighbouring healthy brain-structure; after this we have absorption of the clot, and more or less attempt at reparation: it may be that some inflammation may take place around the clots, which may retard the process of recovery.

If you were called upon to treat a case of this kind from the beginning, what course would you adopt? If you can clearly make out that the lesion is not inflammatory, but, on the contrary, due to defective nutrition, the less you interfere the better. Keep the patient in the horizontal position, with the head a little raised; let the head be kept cool; unload the bowels in such a way as will involve the least effort on the part of the patient: a large turpentine and castor-oil clyster is generally more expeditious than purgatives given by the mouth. Bleeding is generally not admissible in such cases as this, as it

tends to increase the atrophic condition of the brain, and would, under such circumstances, favour rather than repress hæmorrhage.

When this patient came under treatment in the hospital, we did not at first administer any medicinal agent: he was kept quiet and nourished moderately. After one or two trials with the galvanism we observed, on one occasion, a little more excitability in the palsied limbs than in the sound under the influence of the inverse current. Finding that he had made no progress for some days, I was led, from this effect of the galvanism, to fear that some inflammation might have set up around the lesion; and, accordingly, I was induced to give him drachm doses of the solution of the bichloride of mercury—that is, as you know, the sixteenth of a grain of that salt three times a day. No good effect followed this treatment: on the contrary, I fear the salivation which took place sooner than might have been expected must have made him more susceptible of the poison of erysipelas.

After all, I must acknowledge that in this part of the treatment somewhat of the *nimia medici diligentia* was exhibited. It is a lesson hard to learn, and more difficult to act upon, that nature can do more than the physician; but it is a lesson which each succeeding year of increasing experience will impress upon you, and in no cases more than in those of chronic affections of the brain.

I had intended to have brought under your notice to-day another case of the same nature as Ware's, in which apoplectic effusions took place on both sides; but, as I fear I could not do so without making this lecture too long, I shall make this case the subject of my next lecture.

THE AFFAIRS OF THE MEDICAL PROTECTION OFFICE.

At a Meeting of the Leeds Members of the Medical Protection Office, London, Oct. 21st, 1850, George Wilson, Esq., in the chair, it was moved and seconded, and unanimously resolved, "that Mr. F. W. Brearey be requested by the agent to furnish the Leeds members with a full statement of the affairs of the Medical Protection Office to the close of his management, and that in the meantime no further accounts be supplied by the agent here, and that all monies collected by him since the 14th of Sept., on account of the Leeds members, be retained in his hands; and that this resolution be inserted in the Medical Gazette, the Lancet, and the Medical Times. The meeting adjourned until the accounts required be furnished.

Original Communications.

A SUPPLEMENT TO
SOME OBSERVATIONS ON THE
MUSCULAR CONTRACTIONSWHICH OCCASIONALLY HAPPEN AFTER
DEATH FROM CHOLERA.*Containing a notice of a case of Apoplexy,
after which similar Motions were re-
marked.*By WM. FREDERICK BARLOW, M.R.C.S.
Resident Medical Officer to the Westminster
Hospital.

[Continued from p. 600.]

It would, as I have hinted on a former occasion, be obviously of great interest to inquire into the condition of the muscles after death in cases of cholera by means of galvanism, for though the plan of percussion has been known to succeed in producing action, it would be absurd to use it for any precise or delicate purposes, in the place of an agent so subtle, so powerful, so sure, and effecting the mildest or most violent results in strictest obedience to the wishes of the experimenter. It would be desirable to know whether the muscles of those who manifest contractions when life is over, respond to this stimulus with an unusual readiness, and whether there be any ascertainable difference of irritability in favour of those muscles, to take some given instance, wherein they most frequently and energetically operate. It would not be useless to contrast, moreover, the muscular state of those dying in the cold stage and those perishing subsequent to reaction. And the opportunity might be taken of determining the effect which violent and repeated galvanism *might* have, through its exhausting the irritability of the muscles, on the period of the approach of rigor mortis.

I know not whether any observations have been made, by the assistance of galvanism, on the irritability of the muscles during life in cholera. It would probably be found, judging both from the various conditions of the muscular system of the subjects affected by it, and from the great dissimilitude prevailing as to the amount of cramp, to be very different in different cases. The

cause of the cramp may be in greater intensity in one case than another, and so irritate the muscles more, but the state of the fibres which manifest the phenomenon is, doubtless, dissimilar, and so extremely modifies and influences the action of that cause, that it would be preposterous to attempt to measure, as a general rule, the severity of the disorder by the degree of spasm. And, indeed, we know how many have sunk, unresistingly as it were, and as if overwhelmed by some mortal shock, without much suffering from muscular disorder. We must, if possible, so view the state of the muscles after death as connected with that which immediately preceded, as to make one continued history. The most violent cramps have affected the living where the most remarkable movements have stirred the dead; and I am not aware that muscular contractions have ever been noted, save in those who perished in the cold stage of cholera, the decline of which is the decline also of the spasmodic seizures.

I have said, that were galvanism employed to test the irritability of the living in this disease, that most likely the degree would be found very unequal. The amount of a property must, of course, not be judged of by its abnormal manifestation; the healthy who have no cramp, no convulsion, may obviously have more of that peculiar force, whereupon such phenomena depend *immediately*, than those whom they affect. In the former there is nothing to provoke such actions.

On one occasion I passed a very slight galvanic current through the lower lip of a man who lay fast sinking from cholera. The muscular fibres responded readily. Upon that I tried the lowest effectual force, and then applied the same power to the lip of a friend of mine who was by. It had, as far as the experiment could decide, the like amount of irritability. My own lip, on being similarly galvanised, was found more irritable than that of either.

There is, I think, no question more intricate, delicate, and difficult of investigation, than that of muscular irritability; and it is partly made so by its very opposite states in such as really are, or are at least supposed to be, without traces of disease. Modified extremely by the processes of digestion, respiration, circulation, all the delicate and in great part inscrutable operations of nutrition, sex, age, occupation, fa-

tigue, repose, and passions of the mind, is it wonderful that when we come to measure its relations to different individuals, and to the same individual at different times, that we should find our task one of great difficulty? And yet I doubt not that the subject of irritability would be found full of very many new applications by any able inquirer who would be prepared to contemplate the matter largely, and to make experiments with skill and patience.

I have, in the course of my observations, always spoken of the movements which took place after the cessation of the breathing and circulation, as occurring *after death*. Some, perhaps, following those who have written elaborately on what death is, may say that I have assumed the question. It was necessary to employ the word, not so much in a sense of refined philosophy, as in a wide and general meaning. I have used it, not only as people in general, but as the best writers on surgery and medicine are wont to employ it. I may be told that putrefaction has been pronounced as the only sure sign of death, but is not every one who dies, or almost every one, pronounced dead without such testimony? Would a physician, by the side of the dying, on being asked at some given moment if he were dead or no, say that he cannot tell, that he will not be positive until some signs of decay are unmistakably visible? No: he satisfies himself that the so-called "vital functions" are extinguished, and speaks accordingly. I happen to have lying before me Corvisart's work on diseases of the heart. I have made mention of death in the sense wherein he uses it in the following passage:—"I shall freely call the heart the main spring of the human machine; for let its action be suspended but for a moment, and there is apparent death; let it cease altogether, and there is real and sudden death."* Of course we must always have great care to distinguish between suspended animation and dissolution; and in this the stethoscope will be of importance sometimes, as has been strongly insisted on by M. Bouchut. But it will occasionally be impossible for a brief space to distinguish,

let us be as cautious as we will; the real state will be proved by the issue. In such a case we must act as though the dissolution were apparent only, since the nature of that issue may turn upon our own efforts.*

Haller speaks of the *vis insita* of muscles being "proper to life and the first hours *after death*."

Dr. Dowler, in his observations on post-mortem muscular contractions, has drawn attention to a subject of very considerable moment; and I trust it may not be thought superfluous to allude to it. He says,—“Post-mortem contractility, in its legal applications, is not without interest, showing as it does the absurdity of some grave *judicial decisions*, based solely on muscular motion, which latter has been held to be a sufficient proof of life in a new-born child, enabling the husband to inherit the estate of his wife during his life-time.”

It appears to me that lawyers have been placed in difficulty on this point by medical witnesses, and that it cannot be disposed of in the summary style of the American physician. He affirms, speaking of a particular case, that “the Court of Exchequer and the jury decided that the child was born alive, because, when it was immersed in a warm bath, a twitching and tremulous motion of the lips appeared twice.” But in criticising this conclusion, it is only fair to inquire what was the kind of medical testimony which the Court had to guide it. Was it placed in the dilemma of having to choose between contrary opinions? The matter is so weighty that I shall refer to the trial in question, as I find it cited by Dr. Taylor. It was the object of the plaintiff to show that the child was born alive. “Dr. Lyon, the accoucheur who attended the plaintiff's wife, had died some time before the trial; but it was proved that he had declared the child to have been living an hour before it was born,—that he had directed a warm bath to be prepared, and when the child was born gave it to the nurse to place in the bath. The child neither cried nor moved after its birth, nor did

* He adds the following note:—"It will not, surely, be objected to me, that, in death, a capillary circulation still exists for some time; that the hair, the beard, &c., grow in a dead subject; I hope I shall not be thought ridiculous, if I say, a man be dead, although his beard sprout."

* Lord Bacon says, in his "*Historia Vitæ et Mortis*,"—"Ad resuscitandum eos, qui deliquit animi aut catalepes subitas patiuntur, (quorum haud pauci, absque ope, etiam expiraturi fuissent,) hæc sunt in usu." And then, amongst the measures to be employed, he mentions the most generally useful of all, "*Subita inspersio aquæ frigidae in faciem*."

it manifest any sign of active existence; but the two women who placed the child in the bath swore, that while it was immersed, there appeared twice a twitching and tremulous motion of the lips. They informed the accoucheur of this, and he directed them to blow into its throat; but it did not exhibit any further evidence of life. The principal question on the trial was,—“Whether the tremulous motion of the lips was sufficient evidence of the child having been born alive?” The medical witnesses differed. Dr. Babington and Dr. Haighton gave their opinion, that had the vital principle been extinct, there could have been no muscular motion in any part of the body; therefore the child had, in their opinion, been born alive, or manifested life after its entire birth. Dr. Denman gave a contrary opinion: he contended that the child had not been born alive, and attempted to draw a distinction between uterine and extra-uterine life. He attributed the motions of the lips after birth to the remains of uterine life. The jury, however, under the direction of the court, did not adopt this view of the case: they pronounced the child to have been living; and by their verdict the plaintiff recovered the property of which he had been for ten years deprived.*

* See Medical Jurisprudence, p. 610. It appears from this report that, if Dr. Denman's evidence had been admitted, the husband could not have been made a tenant by the curtesy of England. The law draws a clear distinction between the life of the *unborn* and the *born* child. It seems also necessary that the child be born *during the life of the mother*; so that an infant brought quite alive into the world by means of the Caesarean section, would not enable the father, *unless the mother were living* at the time of the operation, to become tenant by curtesy. Blackstone says, “The issue also must be born during the life of the mother; for if the mother dies in labour, and the Caesarean operation is performed, the husband in this case shall not be tenant by the curtesy—because, at the instant of the mother's death, he was clearly not entitled, as having had no issue born, but the land descended to the child while he was yet in his mother's womb; and the estate, being once so vested, shall not afterwards be taken from him.” (See Commentaries, 12th edit., book ii., p. 127.) By the law of Scotland it seems “that curiality or curtesy only takes place where the issue has been heard to cry.” Even the act of *breathing*, the raising of one eyelid, and subsequent convulsions, have not been held enough. (See Dyer's Reports, vol. i., 25, a.) It must be proved that the child *cried*. But according to the English law, “though crying is the *strongest* evidence of its being born alive, it is not the *only* evidence.” “Some have had a notion that it must be heard to cry; but that is a mistake”—(see Blackstone, *opt. et loc. cit.*)—a point very well shown by the case of *Rish v. Palmer*, referred to above, in which, as has been stated, the circumstance of two muscular

The few observations which I shall venture on this history will be made with deference, because of their being directly opposed to deservedly esteemed authority. It plainly appears that the transfer of property, despite long possession, was dependent on the affirmed occurrence of one or two muscular quiverings. The decision rested, be it observed, not on what the medical witnesses *saw themselves*, but on what “two women” reported that they beheld very long back, so that it is impossible to say what was the exact appearance of the movements. There is no reason to suppose that they were voluntary, or in any way connected with consciousness. They were, in all probability, similar to those motions which occasionally happen in the completely dead, speaking of death as we generally view it. They were rather, as I think, evidences of *past* than of *present* life, looking at that complex, perfect life, the life of the body taken as a whole, and as distinguished from mere *local* vitality. Shall we consider *such* quiverings as signs of life, and not go one step beyond, and consider as manifestations of life also those movements of the muscular fibre which may be produced by galvanism long after the latest pulsation of the heart? So long as there is the faintest respiratory movement, or the least perceptible pulsation of an artery; so long as a beat at the heart can be felt, or the weakest sound of it be detected by the stethoscope, a person must be called alive, though just on the verge of death: but is he to be called living because a muscular fibre may chance to quiver? Are we to say of those cholera subjects who manifested such protracted contractions that they did not die till the last was over?

twitches happening upon immersion in a warm bath, and *ten* years previously to the time of trial, and sworn to, not by any medical witness, but by two females, “the nurse and the cook” (as one report declares), were held sufficient evidence of “living,” and to justify a decision in the plaintiff's favour. It may be well to add a passage from Blackstone on Tenancy by curtesy, in order to save the curious reader the trouble of making reference. “Tenant by the *curtesy of England*, is where a man marries a woman seised of an estate of inheritance, that is, of lands and tenements in fee-simple, or fee-tail; and has by her issue, born alive, which was capable of inheriting her estate. In this case, he shall, on the death of his wife, hold the lands for his life, as tenant by the curtesy of England.” See Stephen's Commentaries, Vol. i., second edition, p. 251. See also Beck's Medical Jurisprudence, seventh edition, p. 114. I had not seen the observations in this work, at the time of making the remarks which I have ventured.

To me the distinction which Dr. Denman drew between uterine and extra-uterine life seems a good one, and that which should have guided the Court.* Had the child performed but one act of inspiration the case would have been different; it would have given manifestation of a vital function, as we commonly express it, and have made, moreover, a movement *peculiar to extra-uterine life*. Two twitchings of the lips, which *might, perhaps, have never happened but for the impression of the heat*,† were held sufficient to decide the Court. The law of Scotland would, I am informed, have required proof of crying as evidence of respiration. It may be well questioned whether the question of life or death ought to turn upon the existence or absence of a muscular tremor. We must not, in fairness, call a quivering of this kind a sign of life sometimes, and then reject it at other times as an indication of "living," when it may square with our theories, or suit our convenience so to do. Whatever may be the view adopted by the reader, he will, I am sure, feel the necessity of considering the whole subject of what have been termed post-mortem contractions before positively concluding. He has not simply to ask himself what is life in a scientific and abstract point of view, but to consider what it is as the word is generally employed.‡

The action of the involuntary muscles after the annihilation of consciousness, and the cessation of the breathing, has now been very long observed. It is necessary to distinguish between the action of the heart, or intestines, or uterus, and that mere quivering of fibres, which in nowise reminds one of the special and perfect action of these different structures.

The state of the heart, like that of the voluntary muscles, is modified not by death simply, but by its kind: abrupt dissolution and slow decay leave it, no doubt, most oppositely irritable.§ The physiologist must be cautious of applying

unguardedly the observations made by him on one form of death to another form of it which is completely different.

It is to be reasonably expected, looking to the results of experiments on animals, that the heart in the human subject must quiver, more or less, after some violent and sudden deaths, when neither the touch can discover, nor the ear detect, how attentive soever, the least proof of action; and that the intestines must still persist in their vermicular contractions. Dr. Feldmann observed the heart of a decapitated criminal; the right auricle showed marked contractions on the pericardium being removed. Vesalius, as every one knows, is reported to have remarked a similar phenomenon in the dead body of a Spanish nobleman, and to have been, despite his rare and ardent devotion to anatomy, absurdly and ignominiously banished from a country which should have held him punctiliously in selectest honour.

Intussusception, of which there was no evidence during life, has been again and again discovered after death. Rokitsansky is of opinion that it "occurs during the last moments;" but I think it not unlikely that it may also happen at a later period than that phrase implies. It results, according to him, from unequal irritability of the intestine—an ingenious idea! for it is easy to suppose that one part of it may be lax and passive, whilst another, directly above, is in a state of active contraction. Probably the different states of irritability in different parts of the intestinal canal, which we cannot suppose to be without exception uniformly irritable throughout, may occasionally give rise to intussusception in life-time also, and explain, moreover, certain inequalities or irregularities of rigor mortis. As to the latter point, it may be inferred that the most irritable portions, being the latest to contract, and remaining contracted the longest, may now and then be seen by the pathologist in the form of those partial constrictions which seem more satisfactorily explained by a reference to the effects of rigor mortis than they can be otherwise.*

* Yet how could the Court have decided otherwise than they did, in the face of two such able and distinguished witnesses as Dr. Haighton and the late Dr. Babington?

† I have seen muscles contract on the direct application of heat to their fibres.

‡ The reader will find some definitions of life in a note in the 8d volume of Mr. Palmer's edition of Hunter's Works, p. 126.

§ This has been forcibly insisted on by Mr. Travers in his "Inquiry."

* The reader may compare the observations of Rokitsansky on the production of intussusception with those which have been stated by John Hunter.

Rokitsansky says:—"We naturally ask how the intussusception is brought about, and how its enlargement is effected?"

"The cause is to be found either in the contrac-

The time at which rigor mortis of the heart comes and goes no doubt varies extremely; and the organ is most likely to be found rigid in those cases in which it approaches tardily and lingers long. In some cases it may be presumed to have come and gone before the time of the examination of the body.

The *peristaltic* action of the uterus may very likely endure, in some instances, after respiration has ceased, and so of itself complete a delivery.* I know not whether any observations have been made on rigor mortis in relation to the uterus; but certainly it will not be proper to infer that this organ was contracted before death simply because it is beheld contracted after it. This point must be borne in mind in the examination of women who untimely perish in the parturient state.

Interesting as is the condition of the involuntary muscles after death, and instructive as it would be to consider it more fully, I must leave the subject now. It could not have been properly

tion or moveability of a piece of the intestine, on which account it passes into the adjoining or more capacious tube; or in the extreme expansion or relaxation of a segment of intestine, which gives rise to an inversion of the adjoining narrower or more innervated portion."—Rokitansky's *Pathological Anatomy*, printed for the Sydenham Society, p. 56.

Hunter observes:—"The manner in which it may take place is, by one portion of a loose intestine being contracted, and the part immediately below relaxed and dilated, under which circumstances it might very readily happen, by the contracted portion slipping a little way into that which is dilated; not primary action in either portion of intestine, but from some additional weight in the gut above. How far the peristaltic motion, by pushing the contents on to the contracted parts, may force them into the relaxed, I will not determine, but should rather suppose it would not."—See Hunter's *Works*, vol. iii., p. 587.

Rokitansky would seem to imply, by the phrase "more innervated portion," that the narrowing of the portions of gut which become involved is owing to its being more contractile than that part of the bowel which it enters. How far intussusception may be explained by the unequal irritability of different portions of the intestinal tube will be disputed no doubt; but, unlike what may be said of some assigned causes, it seems capable of explaining the effect in question. It may be imagined that opium could not be given without risk for intestinal spasm occupying some fixed and limited spot, if it had the effect of exclusively paralyzing the affected part without in any way influencing the contractile power of that immediately above it: a condition would in this way be produced very favourable, it may be presumed, to intussusception.

* I have lately, in an experiment, seen the most lively action in the uterus of an animal after it was removed from the body. It is quite clear that the organ can act independently of the spinal cord; but it is thrown into action, as many observations prove, through the reflex function of that organ.

omitted altogether, because the state of the involuntary muscular fibre is as much modified as that of the voluntary by the various modes of dying. A very good illustration of the opposite conditions of the muscles, left by unlike kinds of dissolution, is given by Sir Gilbert Blane, in the Croonian Lecture on Muscular Motion which he delivered before the Royal Society in 1788:—"It is a curious and well ascertained fact, that if a fish, immediately upon being taken out of the water, be stunned by a violent blow on the head, or by having the head crushed, the irritability and sweetness of the muscles will be preserved longer than if it had been allowed to die with the organs of sense entire. This is so well known to fishermen, that they put it in practice in order to make them longer susceptible of the operation called *crimping*. A salmon is one of the fish least tenacious of life, inasmuch that it will lose all signs of life in less than half an hour after it is taken out of the water if suffered to die without any further injury; but if, immediately on being caught, it receives a violent blow on the head, the muscles will show visible irritability for more than twelve hours afterwards."

It may be stated that, in all cases of sudden death, unless they are such as surprise persons either debilitated by long disease, or extremely weak from some cause or other, that the muscular fibre is extremely irritable, although it may not manifest irritability without some stimulant being applied. Abundant evidence of this fact has long been given by physiological experiment. The only wonder is, that the spontaneous mobility of the fibre after certain cases of quick destruction has been so tardy in attracting notice.

I have in a former paper alluded to the twitches of the muscular fibres seen in slaughtered animals. They are matters of popular, loose observation. I have observed them in mice which I have destroyed by carbonic acid and hæmorrhage. I have seen them in frogs many times. They do not appear to be any the more powerful, judging from what I have observed in the latter, from strychnine being administered previous to decapitation. This tetanus-producing poison never, as it seems, acts upon the muscular fibre, unless through the medium of the spinal cord.

As the state of nutrition of the fibre

at the period of experiment, and the way wherein it may have been circumstanced as to rest and exercise, make every difference in regard to the occurrence, extent, force, and duration of the quiverings of the fibres, the latter may, in some sense, indicate in what condition the muscles were, in relation to those matters, at the time of dying. I will sketch an experiment, with the view of illustrating the prevention of any manifestation of irritability by the impoverished state of the muscles. I took a frog which seemed extremely languid, and removed the head quickly; on stripping off the skin, no muscular quiverings were seen anywhere—no, not the faintest: the muscles were extremely pale, flabby, evidently ill-nourished, and some spots were seen here and there upon the fibres, looking not unlike dots of fading purpura.

In observing the state of animals killed by division of large blood-vessels, it is obviously necessary to well distinguish between those *immediate* convulsive motions which depend apparently, as Dr. Marshall Hall has pointed out, on centric irritation of the spinal cord, and those remoter quiverings, very slight and very restricted often, which seem referable to the state of muscular fibre. And here let it be said that there cannot by possibility be a greater contrast of appearance than that between those quick and universal motions which I have seen in animals destroyed by hæmorrhage, and those peculiarly wayward, partial, shifting, often extremely slow movements—quite alike, perhaps, in no two cases—that I have beheld after cholera and apoplexy. No one *could* confound them, unless by actual purpose: they are unlike in form, in rate—unlike, in short, in almost everything in period of occurrence often, being manifested through the muscular fibre.

It may, in the present state of our knowledge, be disputed whether motions of the limbs—such, I mean, as *actually change their position*—do really occur in sequence of death by hæmorrhage, after those convulsive motions are fairly over which directly follow the fatal loss of blood. It may, perhaps, be anticipated, supposing keen inquiry be made, that distinct motions of this kind will, though perchance rarely, be discovered in such a case; but, in watching for such, the greatest care must be taken not to mistake any reflex actions externally ex-

cited for, and confound them with these. I would here refer to some remarks of M. Bonchat, which he makes in speaking of the immobility of the body as an *immediate* sign of death.*

"L'immobilité du corps, c'est-à-dire la cessation des mouvements dans les membres, est un résultat incontestable de l'abolition des fonctions du système cérébro-spinal. Toutefois ce phénomène ne saurait être considéré comme un indice certain de la mort de l'homme, puisque dans un assez grand nombre de maladies nerveuses, l'épilepsie en particulier, il peut y avoir un instant cessation des mouvements musculaires, qui reparaissent lors du retour à la santé. De plus, si les muscles sont immobiles dans leur totalité, dans leur ensemble, de manière à empêcher tout mouvement des membres, leurs fibres se contractent encore partiellement plusieurs heures après la mort, surtout dans les cas de mort violente. C'est ce que Nysten a parfaitement bien établi par de nombreuses observations faites chez les suppliciés. On pourra les vérifier en assistant au travail des bouchers, qui, dans leurs abattoirs, sont tout surpris de voir les fibres musculaires se contracter encore chez un bœuf entièrement dépecé, coupé en deux, et *moné*, comme ils disent, environ près d'une heure après la mort. Ces contractions, qui seraient incapables d'imprimer aucun mouvement aux membres, ont cependant lieu dans les muscles de la vie de relation, c'est-à-dire dans les muscles volontaires, et sont utiles à indiquer, lorsqu'on parle de l'immobilité du corps après la cessation de la vie."

It is quite clear that the observations of Nysten on the great irritability which so long remains to the muscular fibres after death, and the abiding and pertinacious quiverings in slaughtered animals, have not yet been sufficiently applied to pathology. Looking to the principle on which they may depend, it would be most likely erroneous to separate the slight quiverings which merely oscillate on the surface of the muscles, without stirring the limbs, from those strong and striking contractions of them by which the legs and

* See *Traité des Signes de la Mort*, p. 145. It is quite plain that there may be death without immobility, and immobility without death, as cholera and syncope, to go no farther, prove absolutely.

arms are again and again variously moved in different directions, and, occasionally, in a manner which resembles, at first sight, that of the movements which spring from volition. One law, it is probable, includes the two classes of instances: and we may well believe—for there is much evidence towards this conclusion—that in cases of sudden and speedy dissolution, subcutaneous muscular quiverings are infinitely more common than is generally supposed, though, from their feebleness, or the thick covering of integument which invests them, they are invisible. We do not see the muscular twitchings of destroyed animals before we strip their skins from off them; and it is plain enough occasionally, that when we do see them, that we should have no chance of discerning them, unless we first laid the muscles bare. Lately, in watching the twitching of the muscles of an amputated leg, I failed to detect any save in those fibres which were exposed: these were most lively, were renewed at intervals, just as the after-death contractions of cholera are, and were readily excited by pricking or percussion, just as these may sometimes be. It may, indeed, be contended that the exposure to the air excites these quiverings, and that there is no proof whatever of their existence prior to their being laid open to its influence; but it must be remembered that twitches have been seen after mortal asphyxia (in which, be it observed, there must have been loss of oxygen in action upon the fibre than there generally is) without the skin being interfered with, and the most distinct contractions have, as has been amply shown, repeatedly affected uncovered muscles. More, too, is often needed to produce motion than exposure to the air, even where the muscles are very irritable; for frequently all the exposed fibres do not contract: one or two muscles only may be affected, and very restricted portions of these even. Why are these quiverings sometimes so limited, so partial? Are the particular fibres which are active more irritable than the rest, or are they influenced by some stimulus confined to them alone? In speaking thus of the asserted influence of the air, I am very far from saying that it has no power of any kind to cause or to maintain contractions. I would only go the length of asserting that it does not seem at all necessary to bring about

the activity of the fibre in all cases, though in some it may rouse the still muscle, and make the active keep disquiet longer than it would otherwise have done.

Although we cannot, in considering the whole subject, draw an impassable line between the slight quiverings and the remarkable motions, it still remains difficult to explain the reason of the extreme degree of contraction which prevails in some cases. Some aid, as has already been insisted, is undoubtedly afforded by making proper allowance for the various states of the muscular fibre, as to its amount of irritability at the time of death.

Those states, however, will not account for everything. The question has been asked, in previous observations, whether the muscular fibres, or terminal motor nerves supplying them, may not for some time after death be still irritated, in cases of cholera, by the poison of that disease, or the changes of blood it causes, whatever it or they may be? It seems the more reasonable to ask it, looking to what has been remarked in some poisoned animals. Yet we must be careful of attributing any peculiar power to the supposed poison of malignant cholera; seeing that remarkable motions have also followed yellow fever, and keeping in mind the state of the muscles in the case of apoplexy which I have described. This case is, indeed, of especial interest, when we come to argue on the morbid stimuli which, after the cessation of respiration and circulation, may be still supposed to influence the excitable fibre.

As to the slight undulatory motions which play about the muscles of animals just killed by loss of blood, it is quite clear that these cannot possibly be imputed to any morbid material. Does the sudden withdrawal of the impression of the circulation on the muscular fibres, or their minute motor nerves, ever lead to quiverings, just as the sudden loss of blood circulating through the spinal marrow has been held to cause general convulsion?

In our consideration of the property of muscular irritability, we must never forget how variously it may be excited, and how inexpressibly difficult it really is, not so much to affirm what its excitants are, as to assign to them their due and relative power. Its manifestations after death, as during life, may

depend clearly on different causes: now powerful though unseen stimuli may occasion them, though the measure of irritability be not extreme; now slight stimuli may provoke them, because of its amount being excessive; and again they may exist in unusual force, both on account of the power of the exciting cause and the rarely responsive condition of the fibre whereupon it has to play. And though I incline to the belief that the striking contractions which now and then happen after fatal cholera do really no more depend upon any excitement of the spinal marrow, centric or eccentric, than do the quiverings of an amputated limb—which of course cannot be, by any one, referred to it—I confess it far from certain that movements after death in the human subject are *never* referable to impressions made, directly or indirectly, on the spinal cord.

It would save a vast deal of trouble, and appear, at first sight, very consistent, to affirm at once and broadly some simple general principle, styling it a law, and then support it by very unceremoniously twisting some facts, and alone resting on those phenomena, with a cautious partiality, which point in unison towards a particular direction; but this mode of proceeding is not even to be thought of, and the inquirer must rather confess his difficulties, and wait patiently for further evidence, ere he decide on the power and relative power of supposed morbid excitants of the muscular fibre after extinguished life. Meanwhile, however, let him try to explain as much as he is able; more facts will be found in time; and what are now uncertain glimmerings may in the end expand, and brighten into a full, clear light.

The main circumstance in relation to these post-mortem movements is, so far as we can see at present, undoubtedly the *suddenness* or *rapidity* of death: yet, no sooner do we try to account for their occurrence (I speak now of *actual* movements of the limbs), by quick dissolution, than we are met at once by the observation, that as yet they have been seen only after a *few* instances of swift loss of life. This is certainly true when we come to consider how very seldom, except, indeed, in cases of cholera, they have been observed. As yet, so far as I know, they have been noted in one case of apoplexy

only, although this is a disease in which one might think they would have been more commonly beheld. At present there is a dearth of instances.*

The subject is rendered much easier by viewing the slight quiverings, and the changes of position, merely as phenomena which differ in *degree*: still that difference of degree is so extremely marked, that it is not a little difficult to clear up, even on making all those allowances for variations in the condition of the muscles which may be presumed to exist at the last moment. It is one thing—let the remark be repeated—to say that a muscle is so irritable that the least stimulant will act, and another to state clearly the cause of its action. Yet it is certainly a great step to see plainly some conditions which favour, and some circumstances which preclude, any visible manifestations of post-mortem irritability; and no little thing to be able to disabuse our minds effectually of the notion that such as the more remarkable are peculiar to cholera. It may be that they have been so much more frequently observed in this disease from the sad circumstance of its ruthless mortality, which, unhappily, affords us such a multitude of opportunities of examining bodies robbed speedily of life.

It may be said, that if muscular tremors are not seen after death in cases of chronic maladies, wherein the vitality of all the tissues is impaired exceedingly before dissolution, that they are at times beheld very frequent and palpable on the verge of its event, as—to take a good and familiar illustration—in typhus fever. True: but in typhus fever, and some other cases wherein such tremors occur, I apprehend that their presence may be satisfactorily accounted for by

* I find the following passage, by Dr. Hamett, in the substance of the Official Medical Reports on Cholera as it prevailed among the Poor at Dantzick between the end of May and the first part of September, 1831. Alluding to the "morbidity effects," he says:—"The next is the invariable contraction of the bladder; and another, which, although not apparently constant after death from this disease, is seldom or never to be met with after death from others—namely, slight spasmodic contractions or movements, if they may be so called, in the muscular fibres here and there in the body, and more especially in the face and extremities, not only immediately, but some time after dissolution." From the use here made of the word *slight*, and the expression, "if they may be so called," applied to movements, it would appear that Dr. Hamett did not observe the most remarkable kind of contractions which are known to happen. (See the above substance of Reports, p. 57).

supposing the muscles to be agitated by mental influences on the one hand, whilst imperfectly controlled by volition on the other.*

The quivering of the fibres of an amputated limb is as good an instance as can well be given of the action of muscles independently of any influence of the nervous centres; for it takes place under circumstances of separation from them. It may be regarded as an elementary fact ever to be borne in mind in the consideration of certain obscure cases of muscular contraction which we are utterly at a loss to explain. There are instances occurring in which no one, let his acumen and his knowledge of nervous and muscular phenomena be what they may, who could say for certain of some forms of spasmodic action, whether they be centric, eccentric, or referable to some irritation of the muscle itself.

There is, if I mistake not, as much difficulty in accounting satisfactorily for the state of the muscles in cholera during life-time, as in explaining conclusively the various phenomena presented by them after death.

1. Are the cramps produced reflexly by irritation of the mucous membrane of the intestine?

2. Or are they occasioned, centrally, by the blood circulating through the spinal cord?

3. Or are they brought about by changes of the blood-current in the muscles themselves, affecting their fibres or motor nerves?

These are questions which, in my humble opinion, are far more easily asked than answered. They may be as yet pronounced open questions.

I much hesitate to subscribe to the view which has been entertained of their being reflex, because of some points attaching to their form and course, and because, also, of the remarkable rarity of general convulsion in that stage of cholera wherein they exclusively occur.

On the same grounds, too, I think it very doubtful whether they be of centric origin. It is, however, known well

enough that irritation of the cord will produce cramps; and the way in which they not unfrequently forerun, and, viewed properly, foretell incipient diseases of the spinal marrow, is an interesting illustration of the fact. If the altered circulation of the cord itself did really provoke them, is it not inexplicable why the glottis should not be sometimes closed, and the patient either perish from, or be imminently endangered by, passed asphyxia?

The third question cannot, viewed closely, be replied to with a ready and unconditional affirmative, though I think there are facts which make it very probable that the seizures of the muscles in cholera depend upon either direct irritation of its fibres or the terminal motor nerves supplying them.*

One sees a particular muscle in rigid and long maintained action, when—not seldom—scarcely any other is affected at the time. If this contraction be from centric irritation of the cord, it must obviously be applied most partially. When altered states of the blood produce spasms, they generally produce such as are general,—such, in brief, as the poison of scarlatina, or of measles, or variola, brings severally about. No doubt centric irritation will occasionally give rise to most limited movements; but when it does so, it is by influencing a particular spot originating fibres which are distributed to the muscles, or muscle, or even portion of muscle, which may be affected. Reflected irritation may be held more reasonably to explain these cramps; but this mostly displays itself in a different form to that which marks the cramps of cholera, and is so prone to produce general convulsion, that one, as I have said above, can scarcely wonder that it does not do so in cholera at times, if really it be the cause of the muscular disturbances. But why, as the blood, poisoned throughout, pervades all the muscular fibres of the body, are not the cramps universal? Because, it may be, those fibres are variously irritable. Galvanism will not affect, in some cases, all the muscles of the body equally. Cramp has an extraordinary partiality for the muscles of the calf of the leg. Certainly there are none, as a general rule, more

* See an Essay by the writer on Some of the Relations of Volition to the Physiology and Pathology of the Spinal Cord, MEDICAL GAZETTE, vol. for 1846.

† I have never seen what could be properly called a general convulsion in the cold period of the disease. Once in the subsequent feverish stage, I saw a patient who had some time been comatose die in a true fit of epilepsy.

* Dr. Wilson has very especially insisted on the action of the blood on the muscle itself as a cause of spasm. See his work on "Spasm, Lamguor, and Palsy."

often used, more fully nourished, than these are; and there are none which may be supposed in a condition, therefore, to respond more lively to any morbid impression.

Why, again, if the muscles be so influenced by the blood as to contract, and even become pertinaciously rigid, is the *heart*, the principal and most irritable of all, exempted from a seizure which would soon destroy? It is in vain for me to essay an altogether conclusive answer to this hard inquiry; but let it be here well remembered that a stimulus—galvanism to wit—which may most powerfully affect the voluntary muscles will very inferiorly influence the involuntary.*

We have been hitherto far from fully appreciating, and still farther from fully applying, the facts which we know relative to the excitement of muscular action in demonstrable independency of the nervous centres: I say not of the terminal motor nerves.

The effect of altered states of the blood in producing general convulsion is clear enough, though by no means at present adequately investigated; but far less explored has been its influence in the production of cramps and certain partial spasmodic maladies. "A fit of the gout," says Heberden, "has been judged to suspend the power of cramps; but I am much more strongly convinced that the gout is apt to breed and foster them."†

One of the most remarkable circumstances in the history of cholera is the different degrees of cramp. Some, during last year's epidemic, fell unresistingly, and experienced hardly a pang: they died as people overwhelmed by violent, irrecoverable shock. Others were racked most piteously: no trait was wanting to make more perfect their finished picture of severest agony. The muscles, defying all rule completely, were gathered here and there into hard, conspicuous knots; the limbs were strangely distorted, and effectually fixed; the features, just, perhaps, as the will would have directed, or emotion influenced them, were locked rudely in terrible grimace; and the enfeebled irrita-

bility of the seats of spasm gave the only respite.

The whole state of the nervous system also varied greatly. Let us for a moment bring to memory the condition of the brain. Some lay in a silent prostration, which might, perchance, be mistaken for coma at first sight,—lay, not moving a muscle, save when some pain distressed, some want was urgent. Their case, not without parallel, was comparable to that which we see almost daily in fatal burns, wherein the mind and body seem prostrated together and alike.* But in other instances there was, on the contrary, an extreme restlessness, which gave way to nothing, save one—mortal anodyne,—a fruitless, unrestrainable exertion to be remarked often in the sinking state, and making it the fleetest. I was much struck during the past epidemic by many instances in point; amongst others, by that of a young Irishwoman, who, in the prime of life, and, to all appearance, most desirous of living, rapidly perished. Hers was one of the too numerous cases which reminded us, "*remedia tardiora quam mala, et ut corpora lente augescunt citò extinguuntur.*"† Her lively temperament, contrasting with the palpable, fatal collapse, was manifested from time to time by a singular and marked vivacity of manner, by "an inquietude and restlessness which aggravated the ineffable prostration of her strength."‡ It was, indeed, impossible to help closely contemplating the mental condition of some patients, with their circulation so shocked; their respiration so imperfect; their blood so damaged! Wonderful to see the signal difference between the mind and body! Wonderful to see thought, will, emotion, thus active, thus enduring! Could we imagine some livid corpse to speak, move, "glare with unspeculative eye," we should hardly picture a more marvellous spectacle than the mind unsubdued by the destroying pestilence,—when the keen anatomy of the features dismally shrunken as by long disease; the body shrivelled, livid, earthy cold; the hoarse, almost inaudible voice, now whispering of the quenchless thirst, now of the tor-

* See Commentaries, fourth edition, p. 342.

† L'irritabilité est la même partout; elle ne varie qu'en intensité dans les différents muscles, mais elle n'obéit pas aux mêmes stimules dans tous les muscles.—See Œuvres de Legallois, tome i. p. 222.

‡ Tallmen as cited by Dr. Chambers.

turing cramp; the sighing, irregular, long-pausing breathing, ever threatening to fail; the languid heart; the pulseless wrist; and all the symptoms of the disease combined to prognosticate swift dissolution.

Let me now for the present conclude these observations, which have reached already to an unexpected length. Whatever errors of reasoning may be found in the few comments I have ventured, will, I hope, in consideration of the manifest difficulties of the subject, be viewed indulgently. Every phenomenon which manifests or illustrates that force whereby the muscles immediately contract is of considerable interest: and the (so-called) spontaneous manifestation of it after death is of unusual attraction, owing to the circumstances under which it occurs. Unexpected by the generality of observers, it is apt to take them at a disadvantage, and, perchance, to hurry some of them into erroneous inferences.

But the whole subject of that power whereby the muscles act directly, deserves, though it may obtain not, the most general study. No wonder that it so occupied the severe attention of the great intellect of Haller! Imagine the innumerable fibres, voluntary and involuntary, which, through changes so infinite, and a time so protracted, it never refuses to supply with energy! Imagine the sources of its renewal, the modes of its disturbance, the causes of its exhaustion, and all the purposes whereunto it is devoted and adapted—some vital, others essential to life's noblest ends! Mark it exemplified in the contractions of the heart, the expression of the features, the working of the hand; now note it in the tardiest thing that crawls; now in the swiftest that flies through viewless air! Think only of the manifold uses to which it is converted throughout the life of animals in its every form! Can we ever behold with incurious eye any demonstration of this pervading, indispensable force, wherever or whenever we may perceive it? Shall we not rather diligently contemplate it under every circumstance, and try to class truly the minutest movement which it possibly can cause, no matter how unmeaning it may seem at first sight, with those of its own kind?

Westminster Hospital, Oct. 9, 1830.

ON NARCOTISM BY THE INHALATION OF VAPOURS.

By JOHN SNOW, M.D.

[Continued from page 327.]

PART XV.

Detection of ether in the expired air after inhalation—Detection of alcohol in the expired air after it had been taken into the stomach—The effects of chloroform and ether prolonged by causing the exhaled vapour to be re-inspired.

In my last communication it was shown that the vapour of chloroform can be detected by chemical tests, as it exhales from the blood in the expired air. The strong odour of ether, which continues to be perceived for hours in the breath of persons who have inhaled it, is a pretty good indication that this medicine is exhaled from the blood in a similar manner. I thought it desirable, however, to have a more material proof of the fact, than that afforded by the odour, and therefore contrived and performed the following experiments:—

Exp. 58.—As a preliminary measure I passed the expired air for twenty minutes through strong sulphuric acid, inspiring by the nostrils, and expiring by the mouth, through a spiral tube immersed in cold water; a continuation of this tube afterwards dipping into half an ounce of sulphuric acid contained in a bottle. The acid was afterwards boiled in a small retort, the beak of which communicated with a gas receiver under water. No gas was obtained beyond the air expelled from the retort by the heat, and the acid was not changed in colour.

Exp. 59.—On the following day—August 1st, I inhaled three fluid drachms of ether gradually, in the course of four minutes, and was rendered almost unconscious. After waiting for a minute, in order that the lungs might be entirely emptied of the vapour remaining at the conclusion of the inhalation, I commenced to pass the expired air through sulphuric acid, the air first passing through a spiral tube immersed in iced water, to condense the watery vapour, as in the last experiment. This process was continued for twenty minutes. A

few hours afterwards the sulphuric acid was placed in a small retort, the beak of which communicated with a receiver under water, and was heated with the flame of a spirit lamp. It was gradually rendered quite black by the heat, and 11·3 cubic inches of gas were obtained in the jar. The jar being transferred to the mercurial trough, and solution of caustic potash being introduced, the contents, after standing for an hour or two, and being agitated occasionally, till no further reduction of bulk would take place, were diminished to 8·9 cubic inches, showing an absorption of 7·4 cubic inches of carbonic acid gas. The jar being reversed, and a lighted taper being applied to its mouth, its remaining contents took fire, and burnt with a bluish flame. As 2·6 cubic inches of air were contained in the retort at the commencement of the process, the quantity of inflammable gas was probably 1·8 cubic inch.

Exp. 60.—On August 2nd, I again inhaled three fluid drachms of ether, and proceeded exactly as in the last experiment. The sulphuric acid was rendered black as before, and 7·6 cubic inches of gas were collected in the receiver. Potash absorbed 3·2 cubic inches of this, and the jar being reversed, and a lighted taper applied to its mouth, the remaining contents burnt with a flame which gradually descended in the jar to the surface of the mercury. Allowing for the air expelled from the retort, the quantity of combustible gas was 1·6 cubic inch.

Exp. 61.—In order to ascertain the nature of the inflammable gas produced, another experiment was performed, on a subsequent day. The same quantity of ether was inhaled, and the expired air was passed through sulphuric acid in the same manner. The acid was boiled in the retort, until 7·1 cubic inches of gas were obtained in the receiver, when the process was stopped. Solution of potassa being agitated in the gas absorbed 3·5 cubic inches. Two cubic inches of oxygen gas were added to the remaining 3·6 cubic inches, and a portion of the mixed gases was transferred to Dr. Ure's eudiometer. As it did not explode with the spark from a small electric machine, a small quantity of pure hydrogen gas was added, when explosion took place with the following result. The quantities are in hundredths of a cubic inch:—

Hydrogen	3·0
Oxygen, &c. . . .	21·0
Total	24·0
After explosion . .	16·5
Loss of volume . .	7·5

being a diminution of three parts more than the hydrogen would occasion. The remaining 16·5 parts were agitated with a little solution of potassa, when a further diminution of about six parts took place; a little more than ten parts being left. This result shows that the inflammable gas under examination was carbonic oxide, which, in becoming converted into an equal volume of carbonic acid, consumes half its own volume of oxygen. The beak and upper part of the small retort contained 1·9 cubic inch of air, which would be necessarily expelled into the gas receiver, and when this and the oxygen afterwards added are subtracted, the remainder is in the same proportion, very nearly, as the carbonic acid produced by the explosion; consequently the gases obtained by heating the sulphuric acid were carbonic acid gas, and carbonic oxide.

In these experiments, the ether passing off in the expired air is in part absorbed by the sulphuric acid, and on the application of heat is decomposed into various products; the above gases being given off, and free carbon remaining in the acid, and rendering it black. Sulphurous acid gas is evolved, but is absorbed by the water. On adding a few minims of ether to half an ounce of sulphuric acid, and operating in the same way as in the above experiments, the same products were obtained. Alcohol, when heated with a large excess of sulphuric acid, yields the same products as ether; but as I had taken no kind of fermented liquor before inhaling the ether in the above experiments, these products must have resulted from the sulphuric ether.

From the general resemblance between the action of alcohol, ether, and chloroform, and from these substances being governed in their action by some of the same general laws, as previously shown in the experiments on frogs and fishes,* it might be expected that since chloroform and ether can be shown to pass off in the expired air, alcohol would also

* MED. GAZ., last vol., p. 622.

be exhaled in the same manner. Common experience, so far as the sense of smell is concerned, is in accordance with this view. Leibig, however, says,* "according to all the observations hitherto made, neither the expired air, nor the urine, contains any trace of alcohol, after indulgence in spirituous liquors." This, so far as I know, was true as regards the human subject, but Dr. Percy† had obtained alcohol by distilling the urine of a dog, to which he had given a fatal dose of it.

Feeling a strong conviction that alcohol must pass off in the breath, I have made many experiments during the last twelvemonths, with a view to detect it. At first, I caused the expired air, after spirit had been drunk, to pass, for an hour or longer, through a spiral tube, immersed in ice and salt, but did not succeed in detecting alcohol in the condensed water. A little reflection, however, made it evident that alcohol could only exist there in extremely minute quantities; for the spirit which had been taken, being equivalent only to two ounces of absolute alcohol, the inspired air would only be able to take up about a two-hundredth part as much vapour of alcohol as would saturate it, at the heat of the body; and it would be in vain to attempt to reduce the air to such a low temperature as would cause it to deposit any part of so relatively small an amount of vapour; in other words, the alcoholic dew-point of the air must be lower than the temperature of the ice and salt, and, consequently, all the spirit that could be arrested would be that which might be attracted by the small quantity of condensed water. By collecting together the water condensed from the breath in six different experiments, I succeeded, however, in obtaining spirit in a pure state, as will be detailed further on.

In the following experiments the same method was employed, as detailed above, for the detection of ether.

EXP. 62.—August 6th, 1850. Two ounces and a half of rectified spirit of wine, of 80 per cent., were diluted with rather less than a pint of water, and taken, with bread and butter, at supper-time. A slight feeling of inebriation was occasioned by it, but not sufficient to interfere, in the least, with the proper

performance of the experiment. The air was afterwards taken in by the nostrils and breathed out by the mouth, through a wide tube communicating with a metal box containing a spiral arrangement, by which the air was obliged to pass round several times. This box was surrounded with ice. The air was conducted next, by a glass tube half an inch wide, to the bottom of a bottle containing half a fluid ounce of sulphuric acid. The object of condensing the moisture of the breath, in the metal box, was to prevent its diluting the sulphuric acid beyond the point at which it ceases to decompose alcohol when heated. The expired air was, in this manner, passed through the sulphuric acid for thirty-five minutes. Care was taken that no air coming from the stomach by eructation should pass into the apparatus. Two and a half fluid drachms of clear water were condensed in the metal box. The following morning, the sulphuric acid was put into a small retort, communicating with a gas receiver over water, and heated with the flame of a spirit lamp. The acid was rendered quite black, and 5·1 cubic inches of gas were obtained, of which 2·6 cubic inches consisted of air from the retort. The receiver being transferred to the mercurial trough, and a little solution of potassa introduced, 1·65 cubic inches were absorbed. The jar being inverted, and a light applied to its mouth, the remaining contents took fire, the flame gradually descending in the jar to the surface of the mercury. The quantity of inflammable gas was 0·85 cubic inch.

EXP. 63.—Another night the same quantity of rectified spirit was taken, in the same manner, and the expired air passed through the spiral box and the sulphuric acid as before. Six fluid drachms of acid were employed this time, and the process of breathing through it was continued for an hour. Two and a half drachms of water were again condensed in the metal box, and the acid was increased in bulk by rather more than half a drachm. The sulphuric acid was next morning placed in a retort and heated. It was turned black, and six cubic inches of gas were obtained, two of which consisted of air from the retort. Solution of potassa absorbed 3·45 cubic inches of carbonic acid gas, and the remaining contents of the receiver burnt with a slight explosion, on a light being

* *Animal Chemistry*, p. 239.

† *Prize Thesis* "On the Presence of Alcohol in the Brain," &c.

applied. The inflammable gas did not amount to more than 0.55 cubic inch.

Exp. 64.—The same quantity of rectified spirit was taken at night on another occasion, and the expired air passed for an hour through sulphuric acid in the same way as before. The quantity of acid employed this time was a fluid ounce. On the following morning six drachms of the acid were heated in a small retort: they were rendered quite black, and somewhat viscid. 4.85 cubic inches of gas were obtained in the receiver, of which 1.8 cubic inch consisted of air from the retort; potash absorbed 0.6 cubic inch; 0.85 cubic inch of the remainder was transferred into a small jar, to the mouth of which a taper was applied, when the contents burnt for a little time with a bluish flame. To the residue in the receiver 3.8 cubic inches of oxygen were added, and a portion of the mixture was introduced into the eudiometer. As it did not explode with the electric spark, a small quantity of pure hydrogen gas was added, when an explosion was effected with the following result:—

Hydrogen	3.0
Oxygen, &c. . . .	32.0
Total	35.0
After explosion . .	27.0
Diminution	8.0

being a loss of 3.5 more than occasioned by the hydrogen.

Solution of potassa being agitated in the remaining 27 parts, they were diminished to 10; showing an absorption of 8 parts of carbonic acid. The loss of volume was consequently very nearly half as great as the quantity of carbonic acid gas produced by the explosion; and therefore the inflammable gas under examination was carbonic oxide, the amount of which was just one-fourth of the mixed gas introduced into the eudiometer. It is evident on calculation that nearly 1.8 cubic inch of carbonic oxide must have been expelled from the retort, and that this and the carbonic acid were the only gases evolved by the sulphuric acid.

The decomposition which the alcohol, absorbed from the expired air, undergoes in the sulphuric acid is the same as that undergone by the ether in the experiments previously detailed.

Exp. 65.—The water condensed in

the metal box, surrounded with ice in the above three experiments, and in three others not related, amounted together to two ounces. It was placed in a retort, and about three drachms were distilled. This product was placed in a smaller retort, and about twenty minims were distilled into a small test tube. Dry carbonate of potassa was added to this till it would dissolve no more. In a little time, a layer of clear spirit, about the tenth of an inch in thickness, floated on the top of the solution of potash. A piece of asbestos being dipped in this, it burnt with a blue flame. A very little powdered camphor was dropped into a small tube, drawn at one end to a capillary point. This point being brought in contact with the liquid floating on the solution of potash, a little of it rose by capillary attraction, and was observed to dissolve the camphor within. On blowing at the other end of the tube, a minute drop of solution of camphor was forced out, and received on a piece of glass, when the spirit immediately evaporated, leaving a coating of camphor. These tests leave no doubt of the presence of alcohol. The process used in this experiment is similar to that employed by Dr. Percy for the detection of alcohol in the brain and other organs.

Exp. 66.—Two and a half fluid ounces of rectified spirit, of 80 per cent., were diluted with water, and taken at supper-time. The air was afterwards inspired: for fifty minutes by the nostrils, and expired by the mouth, through a glass tube which dipped into three ounces of water contained in a bottle. Next morning the water was put into a retort, and about three drachms were distilled, which were put into a smaller retort, and about twenty minims were distilled into a small test tube. On carbonate of potassa being added in excess, a thin layer of clear liquid floated on the surface. This was proved to be alcohol; for a little bit of asbestos being moistened in it, burnt with a blue flame, and it dissolved camphor in the way described in the former experiment.

Whilst the above experiments show that alcohol is exhaled in the breath after it has been taken into the stomach, a little consideration will prove that only a small part of it can be excreted in this manner. When there are two ounces of alcohol in the blood, the air which reaches the lungs can only take

up, as stated before, about a two-hundredth part as much as would saturate it at the temperature of the blood. At this rate, a person breathing the usual amount of air would only exhale about twelve minims of alcohol in an hour; consequently, if it had to pass off entirely in the expired air, its effects would continue for a very much longer period than they do; and, since alcohol can hardly be detected in the other excretions, it must be decomposed in the system into fresh products.

I have assumed from the first that the speedy subsidence of the narcotism caused by chloroform and ether, in comparison with that from alcohol and other narcotics, depends on the volatility of the former substances, which allows of their ready exit by the expired air. Indeed, the effects of these medicines usually subside in the period which a calculation founded on this view would assign to them. It was previously estimated, for instance, that twenty-four minims of chloroform are contained in the blood of an adult of average size in a state of very complete insensibility; this being about one-twenty-eighth part as much as the blood would dissolve. The inhalation being now discontinued, the fresh air which reaches the air cells will abstract from the blood nearly one-twenty-eighth part as much as it can hold in suspension at the temperature of 100° ; and as each hundred cubic inches of air, when saturated at 100° , contains 43.8 cubic inches of vapour of chloroform, $43.8 \div 28 = 1.54$ cubic inches, or 1.48 minims, will be the quantity removed by the first hundred cubic inches of air which reaches the air-cells. It has been shown that about half the inspired air gets as far as the air-cells; and, supposing the patient to be breathing 400 cubic inches in the minute, 200 cubic inches would act in the removal of the vapour. In this manner it would take two minutes and a half to reduce the quantity of chloroform from 24 to 18 minims, and the narcotism from the fourth to the third degree; after which the effects would diminish more slowly, and in three and a half minutes longer the narcotism would have diminished to the second degree. Then, as the air would only take up about one-fifty-sixth part as much as it would hold, in about five minutes longer we might expect the

return of consciousness; and the slight dizziness or confusion which might remain would subside still more gradually. The above statement expresses pretty well what usually occurs when the inhalation has been kept up for a little time. Children recover from the effects of chloroform more rapidly, on account of their quicker circulation and respiration. Old people, on the other hand, more slowly, for the opposite reason. When insensibility is produced in the course of two minutes for a short operation, and the inhalation is not repeated, the effects of the vapour subside more quickly than stated above; because, at the same time that the chloroform is passing off by the lungs, it is also escaping from the main current of the circulation, by permeating the coats of the small vessels, and diffusing itself in the tissues, and thus allowing the brain to resume its functions.

Ether is more volatile than chloroform; but being also much more soluble, the relative quantity absorbed into the system is so much greater, as to more than compensate for the superior volatility; and consequently the effects of ether subside somewhat more slowly than those of chloroform, the ether taking rather longer to pass off in the expired air.

It follows as a necessary consequence of this mode of excretion of a vapour, that, if its exhalation by the breath could in any way be stopped, its narcotic effects ought to be much prolonged. The following experiments show that such is the case:—

EXP. 67.—About 750 cubic inches of oxygen gas were introduced into a balloon of thin membrane, varnished with solution of Indian rubber in turpentine. The balloon was attached to one of the apertures of the spiral box which forms part of the ether inhaler I employ, and which was used for condensing the moisture in the experiments on alcohol previously detailed. Four ounces of solution of potassa were put into the inhaler, and to its other opening was attached a tube, connected with a face-piece without valves.* After inhaling as much chloroform as I could without

* I used the same arrangement in giving oxygen gas last year, at the request of Dr. Wilson, to a cholera patient in St. George's Hospital. The patient, who was in a state of collapse, was not saved or relieved by it.

being rendered unconscious, I immediately began to breathe the oxygen from and to the balloon, and over the solution of potassa. In this way the vapour exhaled in the breath had, the greater part of it, to be re-inspired. This process was continued for ten minutes, during which time the feeling of narcotism subsided very little, and it passed off very slowly afterwards, about half an hour elapsing before it was quite gone.

The oxygen was used, in this and the following experiments, to allow of respiration being continued for some time from the balloon without employing such an amount of air as would take up a great deal of the vapour. As there was air both in the lungs and inhaler at the beginning of the experiment, the oxygen was not breathed unmixed with nitrogen. The solution of caustic potash was employed for the purpose of absorbing the carbonic acid gas generated by respiration as the air passed to and fro over a large extent of its surface.

Exp. 68.—On another day the same quantity of oxygen and solution of potassa were employed, and fifteen minims of chloroform were placed in the spiral inhaler, in a small glass vessel, which prevented its mixing with the solution of potassa. I then began to breathe as in the former experiment, and continued to do so for fifteen minutes. The effects of the chloroform were gradually induced during the first three minutes, causing a considerable feeling of narcotism, but not producing unconsciousness. After the end of three minutes, the feeling of narcotism remained stationary till twelve minutes had elapsed, and during the last three minutes it very slightly diminished. The experiment was discontinued on account of a feeling of want of breath. It was half an hour longer before the effects of the chloroform were altogether removed.

Exp. 69.—The oxygen and solution of potassa were employed as before, and two and a half fluid drachms of ether were put into the inhaler, with the potash. The oxygen was breathed to and fro over the potash for twenty minutes. The effects of the ether were rapidly developed during the first three minutes, but not amounting to loss of consciousness. From this time, the influence of the ether remained nearly the same to

the end of the experiment, and afterwards subsided very gradually.

The effects of the small quantity of chloroform and ether inhaled in these experiments would have passed off in three or four minutes, if the exhaled vapour had been allowed to diffuse itself in the air in the usual way.

The amount of carbonic acid absorbed by the potassa was determined, and will be given in the next communication, as it forms a separate branch of the inquiry into the action of narcotic vapours.

[To be continued.]

ANALYSIS OF THE FLUID OF HYDROCELE.

DR. DALTON, of Boston, states that he has had an opportunity of examining the fluid of hydrocele in ten cases. The age of the patients varied from twenty-four to sixty years. The amount of fluid varied from three to seventeen and a half ounces. The average amount of fluid was a little over eleven ounces. It was generally clear, and of a yellow, greenish-yellow, or decidedly greenish colour. It was neutral in three cases, alkaline in seven. Its specific gravity varied from 1017 to 1035; the average being 1024.5. In every instance the fluid was strongly albuminous, often becoming quite solid and opaque by the action of heat. In one instance it also contained an abundance of cholesterine, in the form of small crystalline plates, which, floating about in the fluid, and glittering in the light, had to the naked eye the appearance of oil-globules. The fluid of this hydrocele was alkaline, rather large in quantity (seventeen ounces and a half), and of unusually high density (1035); but it presented no other peculiarity. The subject was a large, heavy man, with a dark complexion, rather muscular than fat, about thirty years of age, and in good health. The fluid had been accumulating for four years.

Simon has given the analysis of the fluid of a hydrocele which also contained cholesterine. It was of a yellow colour, without odour, alkaline, and sparkled when shaken, in the same manner as the above. It was also, like the above, remarkable for its density, containing fourteen per cent. of solid ingredient, which, Simon says, is a larger proportion than he has ever observed in any other serous fluid of a similar nature. He reports, also, five other analyses, extracted from various authors. In all these cases, the fluid was albuminous, and, in most of them, alkaline.—*American Journal of Medical Sciences* for July, 1850.

MEDICAL GAZETTE.

FRIDAY, NOVEMBER 1, 1850.

A SUBJECT of considerable interest in relation to the public health has lately undergone some discussion in the daily papers. It has attracted the attention of Government, and has given rise to a Parliamentary paper now before us.* We allude to the new process of *sugar-refining* patented by Dr. SCOFFERN.

We are induced to advert to this subject, because it involves questions of a purely scientific bearing, and on which those only who have studied medicine as physiologists, pathologists, and chemists, are competent to pronounce an opinion. When we assert that the public health is deeply involved in the issue, we think that we have stated enough to justify a notice of this subject in the pages of a medical periodical.

It has been long known that the ordinary process of sugar-refining is attended with considerable waste; and it has, we believe, been established that the new process patented by Dr. Scoffern, which consists in the refining of the syrups by a solution of *subacetate of lead*, yields a much larger product, and at the same time the process of purification is greatly expedited. The subacetate of lead acts in this, as in other cases, as a most perfect defecator. The surplus salt of lead is subsequently decomposed in the syrup, and rendered insoluble by the action of sulphurous acid, which sets free the acetic acid, and, as it is assumed, converts all the lead to sulphite. The sulphite, it is asserted, is entirely separated by filtration, and the filtered liquid gives no indication of the presence of lead on the

addition of the most delicate tests for that metal.

So far the theory is perfect; and we learn from the Report of Messrs. Thomson, Graham, and Hofmann, that in practice on a small scale, brown sugar may be thus refined, and no trace of lead remain in the saccharine liquid.

It became, however, a material question, whether, in the process of extracting or refining sugar on the large scale, and when the means and attention which the process could receive in a chemical laboratory were not at hand, some portion of lead-salt might not remain in the sugar, and affect the health of the consumers? In order to throw some light upon this question, we subjoin an extract from a letter, published in the Parliamentary Paper, addressed by the Governor of British Guiana to EARL GREY, in the early part of the present year. This extract refers to the Reports of Dr. Shier, Colonial Agricultural Chemist, and Dr. Blair, the Surgeon-General, respecting the results of experiments tried by Mr. Lambert, the agent of the patentees:—

"2. The Reports from the Agricultural Chemist prove conclusively that, however beautiful the clarification produced by the subacetate of lead, the subsequent separation of that pernicious ingredient from the cane juice, by means of sulphurous acid gas, cannot be effected thoroughly with the aid which science has as yet brought to bear upon the subject; and, in corroboration of the opinion which Dr. Shier consequently expresses as to the necessity of prohibiting the use of lead salts in the colonies, I further enclose an extract from a letter published in the newspapers by Dr. Wilton Turner, a chemist of eminence, who has for some years been employed in investigating improvements in sugar making, at the cost of individual proprietors in British Guiana, wherein he arrives at very similar conclusions.

"3. In bringing this strong corroboration of the anticipations entertained by the Board of Trade under your Lordship's notice, I am influenced by no

* SUGAR-REFINING: Return to an Order of the House of Commons, dated August 14th, 1850, &c.

desire of impugning the merits of a process which has not only been declared a valuable one by distinguished chemical authorities in Great Britain, but actually adopted in some of the refineries. My object is solely to enforce the necessity of every precaution being taken to prevent disasters from the ignorance or inadvertence of those who might be induced to work under the patent in the colonies.

"4. The properties of cane-juice, in the state in which it is expressed from the cane, are well known to all who have had the opportunity of comparison to be so very different from those of the solutions of sugar operated upon at home, that the fact of experiments proving successful in laboratories there is easily reconcilable with their failure when tried on a working scale on an estate in this colony.

"5. The agent, indeed, alleges, in a letter of which I think it right to annex an extract, that 'the presence of lead in the particular sample of sugar analysed by Dr. Shier might be traced to causes entirely extraneous and accidental; but if a gentleman who has devoted his time and attention to the process is liable to encounter such obstacles, it is frightful to conceive the consequences which might ensue, were it left in the hands of the class of persons usually employed in the manufacture of sugar in tropical countries.'

Dr. Shier furnishes in his report the following plain statement respecting the mode in which the experiments were conducted:—

"On the occasion of my visit to plantation 'Hope,' where Mr. Lambert had facilities which but few of the estates of the colony could afford, I saw Scoffern's process applied on the large scale. Mr. Lambert conducted the process with great ability, and strictly in accordance with the requirements of the Specification. Excess of lead salt was employed, and sulphurous acid gas was transmitted through the clarified and filtered juice for the removal of the excess of lead, till the test and counter test recommended in the Specification warranted its discontinuance. Carbonate of lime was then added, and the juice, after a certain amount of concentration on the copper's wall, was filtered a second time, and the evaporation was

finished in the vacuum-pan. The product was struck into the pneumatic washing apparatus in use on the estate; and, after the first exhaustion, the sugar was washed with less than the usual amount of water.

I was furnished with specimens both of the sugar and molasses, and have subjected them to analysis in the colonial laboratory. I have found lead both in the sugar and molasses, but in larger quantity in the latter.

It appears to us, that there could not be in this case any unfairness in the selection of specimens for chemical examination. They were prepared by the agent of the patentees according to the terms of the specification. It does not appear that the agent made any objection at the time to the chemical analysis of these specimens by Dr. Shier, but fifteen days after the date of Dr. Shier's reports, announcing the detection of lead, we find the agent attempting to assign the presence of this metal to causes entirely *extraneous* and *accidental*. Had no lead been discovered, the results of Dr. Shier's investigation would have been taken as a strong proof of the satisfactory nature of the process, but when it was clearly found by the experimentalist, we have *other* causes assigned, and a partially defective apparatus blamed as the source of the adulteration! Now we are sure our readers will agree with us that it was the agent's duty, either not to allow a chemical examination to be made, of specimens liable to contain lead, from "accidental causes" "or defective apparatus"—or if he did allow them to be taken for the purpose of analysis, he cannot withdraw from the conclusion that the process is defective, and that even when conducted *by himself*, "with great ability, and strictly in accordance with the requirements of the specification," the products are liable to contain lead.

The conclusion arrived at by Dr. Shier, the colonial chemist, is, "that

the use of lead-salts in clarifying cane-juice is *unsafe*, and that they would be doubly so in the hands of such workmen as are usually employed in the colony."

Dr. Blair says:—

"It is therefore my opinion, that the admixture of an aliment so variously, extensively, and continuously used as sugar with any preparation of lead, must be followed by disastrous consequences to the health of the consumers."

Dr. Wilton Turner, another colonial scientific authority, takes the following common-sense view of the matter:—

"The beautiful clarification produced by the sub-acetate of lead has long been known. It not only separates the proteine compounds, but at the same time throws down the acids of the juice and the colouring matter, so as to leave the juice of good canes little inferior to a solution of sugar in water. This juice is, however, contaminated with lead; and the object of Dr. Scoffern's process is to effect its complete separation. If this cannot be ensured, however we may regret abandoning a method producing so splendid a clarification, it must be done.

"The separation of the lead from the poisonous juice (I can use no milder term) is effected by sulphurous acid gas. Although far from granting that the chemistry of this process be correct to the extent claimed by the patentee, still, by way of argument, let it be allowed that the whole of the lead is rendered insoluble by this re-agent. To complete the separation of the lead, a perfect filtration must now be effected. This is a mechanical process, and, to be perfect, requires the greatest care and attention, even on a small scale. To suppose it could be conducted with the same nicety in the sugar-house, and without frequent failure, would be contrary to all our experience. It would be wrong to say such a thing was impossible, but its realization is highly improbable. The evidence offered by Dr. Scoffern, that such has been effected, though strong, and perhaps worthy of credit, must not be taken as proof that such would be the general working result in this colony. The reverse is so likely to be the case, and the effect of the most minute doses of lead so terrible, when

taken habitually, that all estates using this process should be compelled to brand their casks with the word 'lead.' If, on examination by a properly qualified person, the slightest trace of lead be found, the public safety requires the immediate destruction of such sugar. If the process be used, some such step will be imperatively called for on the part of Government."

It has been objected to the report of Dr. Shier, by those interested in supporting the patent, that he does not assign the *quantity* of lead detected by him. In answer to this he very justly observes:—

"I attached more importance to the establishment of the fact that lead is present, than to determine with exactness the quantity; for that will differ in every different making of sugar, according to the nature of the juice, the skill of the operator, and the suitability of the apparatus employed."

This objection, so far as the use of such sugar by the public is concerned, is unsound. If *any* lead be found, the process is obviously defective, and the quantity then becomes a matter of pure accident, depending on the care used in filtration and the experience of the operator. To put this in a stronger light, we may perhaps state that, in most of the cases of poisoning by water impregnated with lead, the quantity of the metallic salt in a gallon has been too small to allow the proportions to be determined with any accuracy.* It is rather the fact whether the lead be or be not entirely separated that it is desirable to ascertain; and on this point Dr. Shier's results are entirely in accordance with those more recently arrived at in England by Professors Thomson, Graham, and Hofmann.

These reports from the British Colonies induced the Home Government to institute an inquiry into the process, with a view of ascertaining "whether

* See letter by Mr. Herspath, *MED. GAZ.*, Sept. 20th, 1850, p. 518.

the separation of the lead be so effectual that the patent may be used with safety to the public."

The inquiry appears to us to have been conducted with the greatest fairness to all parties. Three professors of chemistry—i. e., Professor Thomson, of Glasgow; Professor Graham, of London; and Professor Hofmann, of the Royal College of Chemistry—were selected to make the chemical investigation: and three other gentlemen—Drs. Pereira, Taylor, and Carpenter—were requested to report medically on the results arrived at by those chemists.

The Parliamentary document now before us contains the reports of the Commissioners; and, in another article, we propose to lay the substance of them before our readers. We shall only remark at present that lead was discovered in the sugar and treacle prepared by the patent process in a quantity sufficient, as it is alleged, to endanger public health. The writers of the city articles in some of the daily journals, resting their case upon a letter published by Mr. R. WARINGTON, the pharmaceutical chemist of Apothecaries' Hall—a gentleman employed by the solicitors to the patentees—allege that the process is perfectly *safe*; that no lead exists in the sugar when *properly* made; that if any lead be by accident left in the sugar, it is as harmless as chalk, &c. Upon the authority of Mr. R. WARINGTON, of Apothecaries' Hall, and Dr. Gregory, of Edinburgh—whose curious experiments on the fattening properties of *sulphate of lead*, when given to rabbits, we lately noticed*—some of the newspaper writers have decided that the Government reporters have committed a series of mistakes both as to their facts and their inferences. In short, they contend that the Government should allow the experiment of producing lead-colic on a large scale in

this country, by the public sale of "*lead sugar*," to be fairly tried. There is a vulgar prejudice against knowingly taking even homœopathic doses of lead in any article of food; and, having the weakness to share in this prejudice, we propose at another time to consider whether the Government has not acted with wisdom and prudence in putting a check on this mode of refining sugar, by trusting to the opinions of persons who can have no prejudice to mislead them, in preference to acting on the loose statements of individuals interested in supporting only *one* view of this question, and that view, as we believe, fraught with great danger to the public health.

We elsewhere* publish a case in which a deliberate attempt was recently made to perpetrate robbery by the use of chloroform. We quite agree with our intelligent correspondent, Dr. Snow,† that many of the accounts published of attempted street robberies by the aid of chloroform, are to be regarded as ingenious inventions on the part of the complainants. In this instance, however, there can be no doubt that chloroform vapour was used; and the miscreant would have succeeded, perhaps in taking the life of the prosecutor, but for the alarm which, after a violent struggle, he was able to make.

This case suggests one or two points for reflection:—1. The placing of some reasonable restrictions on the sale of chloroform; and 2. An alteration in the law so as to secure a proper amount of punishment to the offender. With regard to the sale of this drug to the public, we have reason to believe that in the proposed Sale of Poisons Restriction Bill, chloroform will be included.

It appears that the prisoner in this case procured two bottles of the liquid

* See MEDICAL GAZETTE, August 20, p. 272.

* See page 772.

† MED. GAZ., vol. xlv. page 227.

at the shop of a druggist at Carlisle. It never occurred to the druggist who sold it, that a request made by a stranger to be supplied with such a large quantity of this drug, was of itself a most suspicious circumstance. We are informed that he procured it "without difficulty;" and any robber or assassin who requires chloroform in aid of lawless violence may equally procure it at any time. Considering the insidious use which may be made of chloroform in the perpetration of robbery, rape, and murder, this part of the liberty of the British subject ought, in our judgment, to be immediately restricted by some legal penalty. The prosecutor in the Kendal case nearly lost his life: a few minutes more might have put it out of his power to struggle, or to raise an alarm. An inquest might have been held, and, from the absence of the visible effects of poison, or marks of violence on his person, and from the presence of congestion in the bloodvessels, a jury might have come to the conclusion that the reverend gentleman had died from a sudden attack of apoplexy,—from fright, or by the visitation of God.

The present state of our law appears to us to be wholly inadequate to repress this form of Thuggism. It has been long known that narcotic drugs have been used by criminals for the purpose of more effectually perpetrating rape or robbery: it is a new and fearful mark of crime to employ a poisonous *vapour* which is likely to lead to death as certainly as the application of a ligature round the neck. When attacked during sleep, no person can be prepared for resistance; and although the stimulating effects of the *vapour* may arouse the individual, it will, perhaps, be too late to enable him to contend successfully against one or more criminals who have him so completely in their power. In what respect this mode of assailing a person differs from attempted strangulation or drowning, we do not know,

except that it indicates a more artful and ruthless method of disposing of a victim, and at the same time it leaves upon the body no marks of murderous violence.

According to English law, it is not a felony to administer poison to another, or to attempt to drown, suffocate, or strangle a person, unless the *intent* be to commit *murder*. A criminal may administer opium, cocculus indicus or chloroform-vapour, to another, with what amounts to comparative impunity, provided his *intent* be to *rob* or *ravish*, and not to murder. Thus the Kendal assassin *de facto*, if not in legal intent, has escaped at the Appleby sessions with *eighteen months imprisonment*! His offence was not felony; and we presume that he could not have been tried under the statute of poisoning, simply because he intended to *rob* and not to *murder* the prosecutor. This is surely a great defect in the law, if the Cumberland magistrates be correct in their view of it, and one which, for the security of the public, should be speedily remedied. If criminals wilfully employ deadly drugs to aid them in perpetrating rape and robbery, and thus inevitably place life in danger,—often as great as if a knife or a pistol had been used,—the punishment for a mere assault or misdemeanour is wholly inadequate to the offence. As our correspondent suggests, had the prisoner been caught in the act of sulphurising Sir James Graham's pheasants in Netherby Woods, instead of coolly chloroforming a venerable dissenting parson at an inn in Kendal, he would probably have had a much more severe sentence passed on him! We cannot distinguish this act from bow-stringing, throat-cutting, or any other nocturnal form of Thuggism where the intent is to murder, and which the law visits with death or transportation.

Some years since an assault was committed, at

England, on a commercial traveller while asleep. The intent was to rob, and to conceal the act of robbery by murder. The prosecutor escaped with his life after a desperate struggle; but the prisoner was convicted and executed. He used a knife or a razor instead of chloroform; but this is only a variation in the means of death; for the vapour of the drug thus forcibly and secretly administered during sleep may as seriously endanger life as the use of a weapon.

In the *Times* of Tuesday last we find that a man was tried and convicted, at the Central Criminal Court, for assaulting a person in the open street with an offensive weapon—a kind of elastic band, calculated to produce strangulation. The object was clearly to rob the prosecutor, and not to murder him, except as an aid to robbery. The prisoner was convicted, and sentenced to transportation for twenty years. How is such a sentence to be reconciled with the eighteen months imprisonment in the Kendal case? Such is the inconsistency in the administration of the criminal law in the north and south of England. One man escapes with a short imprisonment; another is transported for twenty years; and morally, medically, or legally, it would be impossible to point out any substantial difference in the two crimes. Chloroform vapour may place a man's life in jeopardy as much as a rope or a ligature applied directly to his neck. In the case of attempted strangulation, the punishment was not too severe; while in the attempted poisoning by chloroform there has been, we consider, a complete failure of justice. It is felony to administer to a woman drugs with intent to procure abortion, whether the abortion take place or not: and if we wish to suppress English Thuggism it should be made equally felony to administer noxious drugs with intent to commit rape or robbery.

LECTURES
ON THE
MEDICAL JURISPRUDENCE OF
INSANITY.

*Delivered in the Medical School of King's
College, Aberdeen.*

BY ROBERT JAMIESON, M.D.

Lecturer on Medical Jurisprudence in the
University.

LECTURE VII.

When is mental aberration such as to justify its being deemed insanity?—Discrimination of acute and maniacal delirium—Directions for the examination of the Insane—special difficulties—Lunacy certificates—Scottish Lunacy Law, Asylums, and form of certificate—Proceedings under the English Lunacy Act—form of certificate—When is mental unsoundness such as to justify interdiction?—interdiction defined—Scottish and English mode of procedure—grounds of interdiction—Testamentary capacity of the Insane.

YOU have now in the course we have followed seen the condition called Insanity compared with the similar and allied states which most resemble it; we have reviewed the legal doctrines and practice in regard to it—its nosological divisions with their leading characteristics; we have glanced at some particulars in its statistics, and dwelt at length on the physical, emotional, intellectual, and impulsive features of the disease, embracing with various other matters of forensic application, the medico-legal specialities of suicide, homicide, theft, fire-raising, drunkenness, and feigned insanity; let me request your attention farther to the discussion of certain judicial questions connected with the subject, and to various matters that are best considered in relation to these.

When is mental aberration such as to justify its being deemed Insanity?—Although it may have an essential character, insanity is not one uniform manifestation of psychical or physical inefficiency. Sometimes it is intellectual defect (imbecility—amentia), sometimes intellectual disorder (delirium—mania), sometimes destruction or loss of faculties (dementia), sometimes permanent but particular incapacity of judgment (delusion—monomania), and lastly, it may be merely diseased passion and loss of control (moral insanity). It has therefore to be distinguished from intellectual dul-

ness and ignorance, from febrile and temporary sympathetic delirium, from illusion and hallucination, from eccentricity and depravity. It is often associated with physical disorders, and on this ground bears a resemblance to all diseases which have sympathetic mental disturbance combined with them, some of which, as for example hysteria and hypochondriasis, are transitional to insanity, and not very readily to be distinguished from it. Intellectual deficiency is not insanity, unless it be the consequence of congenital defect of the faculties natural to humanity (amentia), or destruction of them by cerebral disease (dementia); the individual must through his whole life have been under the mental capacity of his fellows, or display deficiencies which are unnatural to his former self. Excitement, delirium, incoherence, are insanity (mania—dementia) only when persistent, associated with delusion, and concurrent with physical disorder. Illusion and hallucination indicate the insane condition (mania—monomania), when they cannot, as formerly described, be made subservient to the operation of comparison, when they defy the judgment, and govern the conduct despite of reason and free will. Exalted passion, erratic propensities, and tyrannous impulses, cannot be deemed mental disease (moral insanity), unless they be foreign to the character of humanity, or to the natural disposition of the individual, and the apparent consequences of diseased incapacity of self-control. I shall not recapitulate, however, what I have already said of these matters, but restrict myself to the marks which distinguish acute from maniacal delirium. I have repeatedly known the latter to be mistaken for the former.

In febrile delirium the ravings of the patient are less rapid, less intelligible, less distinctly enunciated, and less related to surrounding circumstances. The mental symptoms have not been the first to attract attention, and they are not the most urgent; there is serious bodily disorder, great disturbance of the circulation, a high temperature, evidence of uneasiness and pain,—probably tremor, feebleness of body, and loss of appetite,—symptoms very unusual in maniacal delirium, in which, on the contrary, at the period of greatest excitement, you find the patient perfectly fit to be out of bed, complaining of no pain, seeming to feel no uneasiness, and manifesting perhaps little thought of food, but neither irritability of the stomach nor loss of appetite. Maniacal delirium partakes more of the idiopathic character, continues an indefinite time, persists after the removal of its supposed causes or associated physical symptoms, and rarely

occurs before the age of puberty. Taking the history of the attack into account, you will not confound febrile or acute delirium with mania, if you satisfy yourself of its sympathetic origin, the great involution of all the powers of the mind, and the evident derangement of the physical as well as the mental functions of the nervous system. Delirium is the superaddition of a mental to a corporeal disorder. The best diagnostics are physical:—psychically the two conditions are much the same. The voluntary control over thought is lost in both, but voluntary motion is, so to speak, *plus* in mania, *minus* in delirium. Emotion is more perverted in the one, more obscured in the other. Perception and conception are confounded in both. In maniacal delirium there is a greater capacity of memory (the retention of impressions), and after recovery, accordingly, a greater power of recollection; a fact not available as a diagnostic, but very useful to be kept in remembrance by those who come in contact with the insane. A person after his recovery from maniacal delirium recollects all or most of the circumstances of his illness, the wanderings of his imagination, the absurdity of his actions, and the treatment to which he was subjected; whereas, he who has been suffering from febrile delirium finds that memory has been through much of the time incapacitated; something he may recollect vividly, something indifferently, but he has an incorrect notion of the time which has elapsed, and much of his illness is a blank in his mind.

Delirium being a state of unsoundness of mind in the fullest sense, is a condition which for the time annuls civil and criminal responsibility.

The Examination of Lunatics.—The testimony given by a medical man regarding the state of mind of one who is suspected to be insane, must be derived from a personal examination. Before the interview you should take care to be furnished with a full and particular history of the case, comprehending the age, social relations, profession, and physical character of the individual; the existence or not of hereditary predisposition, or of a previous insanity, his natural cast of mind, habits, acquirements, and character; his state of bodily health, the date of the appearance of derangement, and the presumed causes of the malady; the first indications of disturbance, the order and succession of symptoms bodily and mental, the difference between his present and his former habits and character, the type of the emotional disorder manifested, and the delusions, if any, by which his conduct is governed; the actions which are most characteristic of his insanity and the mode by which he is

likely or has been prepared to understand the nature of your visit. A complete history as above will save you much trouble, and possibly the lunatic much unnecessary questioning and irritation; and in some instances be of value in estimating the worth of the opinions and observations of relatives, in cases in which corroborative evidence is desirable.

Your introduction to the lunatic should be managed in such a way as to lead him to form no prejudice against you. As a general rule it may be well that he should not suspect your object, but there will be cases undoubtedly in which it would not be improper that he should know the intention of the visit: at all events it is desirable that you should not be an object of his ill-will. In the latter case, in which he is aware that his sanity is canvassed, you should feel, and he should be led to understand this, that soundness of mind is the judgment which you are anxious to have the grounds of forming. You should conduct yourself towards him, so far as the circumstances of his case permit, exactly as you would towards one sound in mind. In all cases where it is possible and proper, your interview with him should be private, without the presence of even his nearest or most interested relative. You should not exhibit timidity, nor hide the feeling under a blustering manner; rather have the presence of some one to protect you. You are to be sympathizing, not patronising. You are to treat him as an invalid, and not as a child, or as inferior in intellect. I am in these directions presuming that the case is one of some doubt and difficulty, and not, as is more usual, one in which the examination is chiefly a formal necessity, and requiring little tact and discrimination.

You may perhaps be able to discover pathognomonic symptoms of mental disease in the aspect and behaviour of the person, to lead you to be satisfied of his condition before he opens his mouth, more especially if he is not an entire stranger to you; but however high you may rate your power of discrimination in this way, you are never to venture a certificate solely on such grounds; you may be misled by stimulation, extreme and unwonted although natural emotion, a state of excitement from intoxication, depression from physical diseases or the influence of drugs and remedies, and the physiognomy of other diseases, as for example, epilepsy, and hysterical or other nervous affections; besides, the grounds of your opinion should be such as others can comprehend and rightly appreciate. Neither are you to be guided solely by the authority and statements of others; these may direct you in your

investigation, and confirm you in your conclusions, and may be cited as forming partly the foundation of your opinion, but you are always to satisfy your judgment by your own observations and examinations.

In most cases, as you are introduced to the individual who has to be examined in your character as a physician employed by his friends who are anxious respecting his bodily condition, you will find it generally most suitable to commence with an investigation of physical symptoms. Notice the conformation of the head, the expression of the countenance; ascertain the condition of the pulse, the state of the digestive function, the feelings in the head, the temperature of the scalp, the disposition in regard to sleep. Encourage him to represent his symptoms of ill health himself, the notions which he attaches to them, and the causes to which he supposes they are owing. These will frequently be obviously of an insane kind. In some cases the physical examination will afford nearly conclusive evidence, independent of the patient's own exposition of his maladies; there may be a pathognomonic countenance—shall we say also, in deference to Dr. Burrows, a pathognomonic odour not requiring to be substantiated? There may be evidence of physical ailment implying mental disorder. Had it been suitable to the objects of this class to speak of the diseases of lunatics, I should have alluded very expressly to a peculiar sort of paralysis, which even in its slight beginnings scarcely ever, or if I speak from my own experience never, exists but in combination with diseased minds. I allude to the paralysis of the insane, which you will find described in all the later writers on mental pathology, and most graphically portrayed in the Croonian Lectures of 1849, by Dr. Conolly.

Your investigation of the mental disorder should consist in a search for those characteristics of unsoundness which have been described. You are to seek for such changes of moral character as nothing but disease can explain; for such instances of imbecility, incoherence, and delusion, as attest imperfect mental power, disordered understanding, and incapacitated judgment, and for instances of conduct incompatible with a healthy faculty of self-control. If the patient labour under acute mania or chronic delirium you will meet with no difficulty, he will save you all necessity of searching, and furnish in a single interview more proofs of insanity than the memory can retain. If imbecility is the type of the disease, you are to look for its indications in the physiognomy, habits, tastes, and general conduct; in the powers of attention, efforts of judgment, and capacity of dealing with thoughts. You must take the

education and the means of acquiring information into account: shrewd examiners have before now mistaken ignorance for imbecility. A person may be more sound in mind than Malvolio was, without knowing what opinion Pythagoras held concerning wild-fowl. If some governing delusion is sought to be exposed, you may perhaps find occasion for all your acumen; for, as you are aware, monomaniacs, if their easily awakened suspiciousness be once aroused, occasionally exert no slight power of cunning and secretiveness. You must, in the first place, do all you can to obtain his confidence; if once you succeed in getting him to converse freely with you, he will gradually become communicative, and come nearer and nearer to the delusion engrossing his mind. If he should fail to do so, try to make some of his singularities and eccentricities a subject of discussion, express an interest in them, and seek for an explanation of them. If he should still fail to expose his ruling delusion, you should, from possessing the necessary key, take a judicious opportunity of introducing the subject yourself, and question him of his belief regarding it. Few monomaniacs are proof against this, however much they may wish to conceal their insane notion. I have never known one directly and persistently to repudiate his delusion; he tries, but does not succeed. When pushed to the point he displays his morbid fancy, or he manifests confusion of thought and incoherence of language in relation to it, or he expresses himself mysteriously and with reserve, or he gets angry, declines to speak on that matter, or sullenly remains silent,—a great effort to him. In all cases advantage should be taken of a lunatic's willingness to write, for even when no characteristics of insanity have been observed in his conversation, you will frequently in his letter or statement find traces of delusion, incoherence, or emotional aberration. By sympathizing with the patient you will usually succeed much better than by the most ingenious attempts to compel a display of his delusion; but sometimes, when other expedients have been unsuccessful, it may be advantageous to accuse him, so to speak, of delusion and insanity, so as to lead him to an explanation and defence of conduct which appears extravagant and irrational. Do not be over-desirous to elicit the fact of insanity according to some pre-conceived plan which you have laid down for the purpose. Allow the lunatic to take his own way of exposing his state of mind; the more the interview assumes the form of monologue on his part, and the nearer his discourse approaches to the form of soliloquy, the better.

Time will not permit me to allude to the

special difficulties that may occur in the examination of lunatics. Here is a common one. You are required to give an opinion on the state of mind of one of whom you know nothing, of whom you can be told little or nothing; that preliminary history is wanting which I have said is of so much convenience. The individual has possibly been found vagabondising, and has been laid hold of by the authorities for some slight offence. There is some reason to think that he was once under confinement as a lunatic, and on this account you are requested to investigate his case in a police cell or the ward of a prison. He is reserved and sullen, replies curtly to questions, but manifests no delusion. You can make little out of him, save that his disposition is by no means engaging, or his intellect very brilliant. In such a case you must endeavour to accumulate some knowledge of him; have him watched and conversed with, and from time to time secretly observed. If you find that he mostly occupies one place and position, that though sullen and dejected he occasionally smiles by himself, avoids his food, that at night he sleeps badly, talks and laughs to himself, stands on the floor, or wanders about his apartment, you have ample grounds for suspecting that he is the subject of some morbid delusion; but as you possess no hint of it, you may have difficulty in getting it evolved. You cannot sound his opinions on all matters of sensation and speculation, but you may chance to jangle the loose string by a judicious venture. I have had occasion to notice, as being more potent than ordinary in conjuring forth a delusion in such cases, questions relative to kindred, bodily health, sexual ideas, poisoning, unseen agency, and nocturnal feelings. There is much room for the exercise of tact, ingenuity, and sagacity, in these cases.

I have known an examiner annoyed and nonplused by the persistent and absolute silence of the person under examination. This conduct may arise from idiocy, insane abstraction, and peculiar delusion, in which instances insanity will be well marked in the aspect and behaviour of the patient. It sometimes is the consequence of mere obstinacy, or of a determination to thwart all attempts at investigation, but in every case it forms, in combination with the testimony presented, a good ground for the belief of the existence of an unsound mind.

The forms of imbecility of mind and moral insanity are perhaps the most difficult of all to investigate satisfactorily; but as we have yet to consider the subjects of civil and criminal responsibility, I shall at present delay no longer on the examination of the insane.

Lunacy Certificates.—The ordinary purpose of the examination of lunatics is to certify, that the condition of the mind is such as to require interference with the patient's liberty for the sake of fitting treatment, his personal safety, and the protection of the community. In Scotland, before an individual can be sent to a lunatic asylum, the fact of mental derangement, together with the necessity of confining the patient, must be certified by an authorized practitioner in medicine. The certificate must be given "upon soul and conscience," and all who are concerned in lodging one who is sound of mind in an asylum, or in compassing the confinement of an insane person in an irregular way, are liable to heavy penalties. Upon such a certificate the nearest relation or recognized guardian of the patient petitions the sheriff of the county to grant a warrant for removing him to a licensed lunatic house. While under confinement he is seen at will by the sheriff or his deputy, accompanied usually by a medical assistant and the procurator fiscal of the district, and he has the power of ordering the liberation of the patient whenever he may deem it unjustly delayed. The minister of the parish has also a right to visit the lunatic asylum, but no power in the way of supervision or inspection. The machinery is therefore simple, economical, and as regards the protection of those under restraint in licensed asylums, not to be charged with being ineffective; but the Scottish lunacy law is very far from being perfect, although from the successful resistance which all the recent attempts at improving it have met, it might be deemed a much more faultless institution than it actually is. Lunatics that are not paupers may be kept anywhere, and treated in any way, by any one. The public hospitals are public in a limited sense, and neither freely available for educational purposes to the profession, nor even for the care and treatment of all classes of the insane. I have known instances of disagreeable or difficult cases being rejected, and a lunatic who has committed a criminal action, and whose safe custody has become a matter of much consequence to the community, is by most of these misnamed public asylums unhesitatingly refused. They are not subjected to adequate government control, but are liable to be under the management of a body of self-elected, irresponsible, ill-chosen directors, nearly as numerous as the inmates. In some cases the hospital is but an appendage to some other institution, instead of being separate and independent, having no governing authority but that connected with the parent establishment, and therefore subject to be ruled as if it were a

prison, an infirmary, or a poor's-house. Patients of various grades are admitted into houses, which in some instances have been originally designed for and are chiefly occupied by insane poor, and are even sometimes rather heterogeneously mixed. It is this proportion of private patients, however small, that constitutes the barrier to the admission of students for the purposes of instruction. The attempt is constantly being made to ape the style of a private asylum, and to increase the number of the better class, to the injury of the full efficiency of the hospital as a public institution, and to the prevention of the establishment of such admirable houses for the better rank of lunatics as are common enough throughout England, but almost unknown in this part of the island.

There is an uncertainty about legal details in reference to lunacy matters in Scotland, which it is desirable should be amended. There is a want of uniformity in the constitution, charges, and arrangements of the hospitals, and if I am not mistaken, in regard to modes of procedure and the forms of warrants and certificates, much is left to the discretionary power of local officials.

The following may be received as an adequate form of a lunacy certificate in Scotland.

(Place and date—the latter in words).
I, A. B., M.D. (or surgeon), hereby certify on Soul and Conscience, that I have this day visited and examined C. D., at present residing at ———, and am of opinion that the said C. D. is in such a state of mental derangement as to require confinement in a lunatic asylum.

(Signed) A. B., M.D. (or surgeon).

In England there must be two medical certificates, unless in the case of a pauper lunatic, when the testimony of one medical examiner is sufficient. These certificates must be signed by individuals not partners together, not relatives of the patient, and having no professional connection with, or other interest in the asylum to which the patient is to be consigned. These examiners have to investigate the case not together, but separately, and must each in his certificate mention the facts upon which his opinion is founded. These documents must be accompanied by a printed order, filled up and signed by the relative or guardian who authorizes the patient's detention as a lunatic. When the lunatic has been received into the hospital he has to be examined anew, and reported upon to the Board of Commissioners in Lunacy. The most important difference betwixt a Scottish and an English lunacy certificate, is the specification of some of the facts on which the opinion is based, in the case of every

lunatic not a pauper, a thing which seems to derogate from the professional character of the document. To give a certificate means, to render a fact sure by the testimony of adequate knowledge; the *ex cathedra* deliverance is by this mode, however, converted into the mere expression of a proposition, and the opinion propounded is not so much a judgment as a condescendence or submission of professional or presumed adequate knowledge to some other, which if surer ought to be at once applied. The medical examiner would appear not to say—this is lunacy; but—is not this lunacy? a function which might be quite as well, and rather more fittingly, discharged by others than “a physician, or surgeon, or apothecary, duly authorized to practise as such.” Much latitude is allowed in regard to the statement of facts: these may be any characteristic symptoms of lunacy, as incoherence in conversation, ungoverned excitement, special delusion, noisy or indecent conduct, alteration of the natural physiognomy, or even facts which have not been observed by the examiner himself, but have been merely represented to him by others, provided this circumstance in regard to them be stated in the certificate. The following is an example of the form adopted.

I, A. B. being a physician (surgeon or apothecary), duly authorized to practise as such, hereby certify that I have this day, separately from any other medical practitioner, visited and personally examined C. D., the person named in the accompanying statement and order, and that the said C. D. is a lunatic, and a proper person to be confined, and that I have formed this opinion from the following facts, the latter being from information derived from his relatives; viz., that he labours under a great despondency of mind, the result of the delusion that he is the victim of a widely extended conspiracy to injure him, and that he manifests a propensity to self-destruction.

Signed A. B.,
(Residence.)

(Date in words.)

In Scotland, where no grounds are required to be assigned for the opinion given that one is insane, and where the community has not the protective supervision of lunacy commissioners, it would be well either that instruction in medical pathology were made a necessary branch of medical education, or that the privilege of granting lunacy certificates should be restricted to those who could declare that they had had the means of studying the disease¹ in some hospital for insanity.

When is mental unsoundness

justified by interdiction?—Interdiction is defined by Briskine, as a legal restraint upon those who, either through profuseness, or extreme facility of temper, are too easily induced to make hurtful conveyances, by which they are disabled from signing any deed to their prejudice without the consent of curators, who are called interdictors, and who are the nearest male relatives on the father's side, if they be of lawful age and otherwise capacitated.

When a lunatic is interdicted he is no longer free to contract agreements, execute legal deeds, or conduct his own affairs. In England, the individual having been certified to be insane by qualified medical examiners, the Court of Chancery is petitioned on this ground to appoint a special commission, to determine whether he be *compos* or *non compos mentis*. This is termed appointing a commission *de lunatico inquirendo*. This commission examines the evidence pro and con, and gives verdict accordingly. In Scotland, the lunacy certificate having been obtained, application is made to Chancery for what is termed a Brieve of Idiocy, or a Brieve of Furiosity, (according as the person is held to be either fatuous or raving mad.) This document is addressed to the judge-ordinary of the district (the sheriff,) and instructs him to summon a jury to determine upon the individual's state of mind, and upon the male relative to be appointed interdictor. The proceedings are instituted by the nearest male relative of proper age, and with the knowledge of the person whose state of mind is the subject of doubt, and are termed “a cognition,” or “cognoscing a lunatic.” The lunatic must be personally examined by the jury previous to their verdict.

Interdiction is justifiable and necessary in all cases of mania, dementia, and imbecility. Cases of difficulty arise in the lesser degrees of insanity, as the earlier stage of mania, the person being not raving mad, but only in a state of more than natural excitement; cases of imbecility, the person being not idiotic, but simply of weak mind, and many instances of monomania. In moral insanity interdiction is presumed to be unnecessary.

In cases of asserted imbecility, take care not to mistake ignorance, from want of education and opportunities of information, for mental defect; in cases of excitement and delusion, be satisfied that the former really interferes with voluntary control, and that the latter is not merely of a speculative and harmless character, but is practically exhibited in insane and ruinous conduct. The mode of investigation must be adapted to each particular case. In imbecility, the individual on whom the question is raised, must have had sufficient education to be capable of understanding the nature of the question.

tion and opportunity to know, comparing his intellect with one cultivated in a similar degree, and if the imbecility be adventitious, the present condition of his understanding with what you can learn of its previous capacity. Test his faculty of memory, his powers of notation, his capacity of being instructed, his knowledge of money matters, of the condition of his affairs, and of the proceedings in progress. Take his moral character into account; see whether or not he have self-reliance and "a mind of his own," or be so facile as to be capable of being led in any direction by the self-interested and evil-designing. Though the capacity of a monomaniac to manage his own affairs is never increased by his delusion, still he may be perfectly competent to manage them, not in an ordinary way merely, but much better than any one else could do for him. Ascertain how his faculties and emotions are exhibited in writing, his ideas regarding matters of religion, morality, property, money, duties, and obligations. Conduct is a much better test than capacity in such cases. Before you can testify that interdiction is necessitated from delusions, be satisfied that they lead into insane and ruinous courses; that they so engross the mind as to render efforts of attention inefficient when directed to other necessary objects; that they lead to neglect of natural duties; that they occasion apathy, indifference, and neglect of worldly affairs, to the lunatic's own loss, and the injury of those naturally dependent upon him, or legally interested in him; or that they are combined with loss of memory, general mental deficiency, or morbid feelings, which lead him to pervert the application of his worldly means. There might be incapacity in business, without there being as a consequence sufficient grounds for interdiction from the management of affairs; mere incapacity to make money, and thereby a livelihood, owing to diseased mind, would by no means form a sufficient plea, although incapacity of keeping, or spending, or using it rationally, might.

Testamentary capacity of the Insane.—For a valid testament there must exist a disposing mind; that is, a mind not oppressed and governed by delusions, in which the judgment is capable of discerning, the memory not clearly impaired, and the emotions not unnatural. No one labouring under mania, amnesia, or dementia, can be deemed to have a disposing mind; but it is presumed that one who is merely imbecile, or labouring under a form of partial insanity, may. Any lunatic may execute a valid testament during a lucid interval of his disease. He is incapable of disposing of his property, if his imbecility of mind is such as to interfere with a right under-

standing of the act, if his delusion obscures his knowledge of surrounding circumstances, and if he labours under any delusion incompatible with right feelings and rational ideas in regard to the disposal of his property. A lunatic who has been interdicted may yet be capable of making a sufficient will, because he may have enough of capacity for doing this, although he have not the degree of mental strength and activity of intellect requisite for this uncontrolled management of all his affairs. Although of feeble mind, the lunatic's imbecility would not be such as on that score to invalidate his will, if he fully and accurately comprehended the extent and nature of his property, if the dispositions in the deed were not only natural but of his own devising, and if he rightly understood the consequences of the document. Nor although the subject of delusion would the lunatic be incapacitated to execute a will, if the provisions in it were rational, in conformity with previous intentions when sane in mind, and independent of the delusion. The character of the deed itself forms usually the best evidence of testamentary capacity. Should a will be written by the patient, without incoherence, irrational, unnatural, or inconsistent provisions, it will be perfectly valid, even although he was at the time undoubtedly unsound in mind, and the inmate of a lunatic asylum. It is not the insanity of the devisour, but the illegality, falsity, or insanity of the deed, that will overthrow it:

EPIDEMIOLOGICAL SOCIETY.

THE arrangements for the working of this Society are proceeding as rapidly as is compatible with the magnitude and extent of its objects. At a meeting of the Council, held at the residence of Dr. Babington, the President, on Friday, Oct. 25, the laws were finally determined upon, and ordered to be printed. The report of the "Objects Committee" (a committee appointed to specify and arrange the objects proposed to be accomplished) was received, adopted, and ordered to be published. A Committee was appointed for general purposes, among which are to be included that of appointing, arranging, and directing sub-committees of special inquiry on various subjects; and it was resolved—"That a Sub-committee be forthwith appointed to investigate the highly important phenomena of small-pox and vaccination." The meeting was well attended, about twenty members of the Council being present, among whom were some of the most distinguished members of the profession.

Actus.

*Oratio Harveiana in Aëthrus Collegii
Regalis Medicorum habita, die Junii
xxix., MDCCCL. A JACOBO ARTURO
WILSON, M.D. Londini, MDCCCL.*

DR. WILSON thus introduces the object of the Harveian Oration:—

"Attendite igitur, socii, hospites, et quicumque huic festo favetis, fratres medici! Nec vereamini, pro hæc saltem vice, aures adhibere in verba, non mei Londinensis, linguæ non mee balbutientis, et Latino pede claudicantis, sed Anglica, Harveiana, ex ore suo ipsius, octogenarii, et, quasi e sepulchro, pro se et suis in omnes ævum loquentis."

"To maintain friendship, there shall be at every meeting, once a month, a small collation, as the president shall think fit, for the entertainment of such as come; and, once in every year, a general feast for all the fellows; and on the day of such feast shall be an oration, in Latin, by some member in commemoration of the benefactors by name, and what in particular they have done for the benefit of the College, with an exhortation to others to imitate, and an exhortation to the members to study and search out the secrets of nature, by way of experiment; and for the honour of the profession, to continue mutually in love."

On which injunction Dr. Wilson remarks, we doubt not with the full concurrence of his audience:—

"Id unum tibi objicio, quod, nata Anglus, in hæc Anglorum concione, pro te, stirpe, moribus, indole (si quis unquam), Anglico, de medicina et medicis Anglicis hæc orationem aggressurus, lingue alienæ, nec mee, nec tuæ, compedibus obstrictus sum."

Without in the slightest degree detracting from the acquirements of the learned members of the College of Physicians, we cannot but express our opinion that it is a real farce that they should, in the present day, be compelled to deliver and listen to topics of present importance in a dead language that has long ceased to be the vehicle for the interchange of thought among learned and scientific men, even of different countries, and it is still more absurd from the mouth of an English orator addressing English physicians!

Dr. Wilson, after alluding to his Har-

veian predecessors bearing his own name, and having paid a tribute of filial respect to his distinguished father, proceeds to discourse—"De rebus hoc proximo anno gestis et factis, equibus aliquid lucri vel damni, honoris vel incommodi, communitati nostro acciderit,—de statu, progressu, et futuris artis medicæ fortunis—de morum inter nosmetipsos disciplinâ et consuetudine."

The first topic to which Dr. Wilson thus refers is one of paramount importance, involving the discussion of conduct on the part of the Executive which has in all probability greatly extended the fatal spread of a fearful pestilence:

"Respice, igitur, in annum vix præteritum, vos, Præses et Socii! qui mecum huic solenni orationi inservitis! In trivis—per vias—per aperta rura—apud ipsas Bænas, qui pover! quantus luctus! quæ frequentia funera! Quæ hæc est immensis morbi species! hæc mortis imago nova? Annus nefastus! Collegio nostro, præ cæteris, heu!—sine gloriâ memorabilia. Annus, in quo, huic urbi insolita et ævis-sima peste diu ingruente, tum poetas universum Angliæ regnum vastante, Collegium hoc Regium Medicorum Londinensium, neque a senatu, neque a consiliariis regniæ intimis, neque a prætoris regio ad res domesticas administrandas designato, ne unâ quidem vice vel voce, in auxilium salutis publicæ vocatum est! Neque in curiâ, neque in fæco, prevalente morbo, vox nostra audita est. A nullis nostri periculum factum est consilii!

"Per orem sanguinem Harveii! Quid est, si hoc non contumelia est!"

We have ourselves on several occasions expressed the strongest disapprobation of the usurpation of the functions of the College of Physicians by a "Board of Works," whose self-sufficiency did not permit them to seek the advice of the body the best qualified to give opinions on matters on which they showed themselves ignorant. We therefore now cordially welcome Dr. Wilson's indignant remonstrance upon the general neglect and ingratitude with which the labours of the profession in the treatment of cholera, have been rewarded.

Dr. Wilson pays a just tribute to the memory of Dr. Burton, of St. Thomas's Hospital, who was one of the earliest and most lamented victims of cholera. Dr. Burton's investigations on the action of lead on the system are duly noticed by the orator.

The loss which the body medical and the world at large (if it would but learn to know the true value of legitimate medicine) has suffered in the death of PNOX, is strongly and eloquently enforced. Dr. Wilson has put the debt of gratitude due to this father of pathological chemistry in as forcible language as he could command; but, in our estimate, words cannot express it.

The evils of quackery are ably exposed by the orator. The gross and insulting treatment of naval surgeons does not pass unscathed.

In recording the merits of Harvey and Lumley, the orator does not forget the labours of living investigators who, following the example of Harvey, devote their energies to the investigation of the blood in health and disease. The character of Harvey's researches is compared and contrasted with the medical inquiries of the present day. The present state and prospects of the College also receive notice. Dr. Wilson concludes in the following words:

"In nostra republica, quid verum est, sit pro re—pro imperio, religio—pro lege suprema, populi salus! Sit unitas in communitate—in communitate unitas!"

"Ad hæc tuenda et conservanda sit nullum inter nos iurandum!—si ullum, in verba hæc:—Experientia!—Amor!—Amicitia!—verba ipsius Harvey—verba omnium ætatum, temporum, laborum! Leges, mores, etiam diplomata regis, humana omnia mutantur. Amor et amicitia a Deo sunt, et manent."

"Veniam date!"

To praise the latinity of this oration is superfluous; its merits were acknowledged by its hearers, and will in no way be disputed by its readers.

Remarks on the Comparative Value of the different Anæsthetic Agents. By GEORGE HAYWARD, M.D., one of the Surgeons of the Massachusetts General Hospital. Pamphlet, 8vo. pp. 11. Boston, U.S. 1860.

THE agents examined by Dr. Hayward are ether, chloroform, and chloric ether. The author decides in favour of ether. "The advantages, then (he observes), of sulphuric ether, as an anæsthetic agent, are its entire safety, the ease with which it is administered, and the slight inconvenience which follows its administration." Dr. Hayward further

states that, after a careful examination of some of the leading medical journals of Europe and America, he has found only one case of death by its inhalation, and that, took place at Auxerre, in France, soon after its discovery, and when the best mode of administering it had not been adopted.

Of chloroform the author observes that its "only advantages are that it is more agreeable to inhale than ether, and that a smaller quantity answers the purpose." On the other hand, he points out that its injurious and fatal effects have been by no means unfrequent.

Of the truth of this assertion our British, as well as the American and Continental journals, can bear lamentable testimony. "With regard to chloric ether," Dr. Hayward very justly observes "that it derives its power of producing insensibility from the chloroform, it contains, and it is difficult to understand how the addition of alcohol can deprive it of its dangerous properties, when it is well known that the mixture of this substance with sulphuric ether, renders it in a great measure unfit for inhalation." Under this impression the author concludes that chloric ether is an unsafe anæsthetic agent.

This short essay deserves an attentive perusal by all who have recourse to anæsthetic agents.

The Anatomical Remembrancer. 4th edition. 12mo. pp. 240. London: Higley. 1860.

FOR the sake of those gentlemen now pursuing their anatomical studies at the medical schools, we lose no time in calling attention to the publication of a fourth edition of this useful little pocket Remembrancer. There is no reason why it should not be always the companion of the student. A glance at it during any leisure half hour,—if such an event really occurs amidst the hurry of lectures and practice,—will not only aid recollection, but impress facts more strongly on the mind, and suggest new subjects of study. The little book is published anonymously; but the fact that it has reached a fourth edition is a very strong point in its favour. It is written with conciseness and clearness, and, as far as we have examined it, with correctness.

Annual Report of the Progress of Chemistry and the Allied Sciences. By JUSTUS LIEBIG, M.D., and H. KOPF. Edited by A. W. HOFMANN, M.D., and WARREN DE LA RUE. Parts IV and V, 1847-8. London: Taylor and Walton.

We are glad to welcome two more numbers of this valuable retrospect of chemical science. No fewer than ten men of scientific eminence are concerned in the preparation of this Report; and from this division of labour, it is easy to perceive that all branches of chemistry have received due attention. We have looked through the two parts now before us, and we can recommend them to all lovers of chemical science as essential to the acquisition of a due knowledge of the progress made during the last two years.

Pathology of the Human Eye. By JOHN DALRYMPLE, F.R.C.S. Fasciculi V. and VI. London: Churchill.

It is some time since we have had an opportunity of noticing this valuable publication, in the production of which artistic skill and practical information are admirably combined. The two fasciculi before us comprise no fewer than forty-seven illustrations of various diseased conditions of the eye. The drawings are as well executed and as faithfully coloured as any which have been published in the preceding fasciculi. In plate 19 there is a coloured drawing, representing the effects of Iritis on the globules of the eyes, which is so skilfully treated that it has quite a stereoscopic appearance. The pathological conditions represented in these two parts are, *Aquo-Capsulitis*, *Iritis*, *Congestion of the Choroid*, and *Glaucoma*. We entertain no doubt that they will keep up the character of the work, and give satisfaction to the subscribers.

Contributions to the Physiology of the Alimentary Canal. By WILLIAM Brinton, M.D. London. Pamphlet, 8vo. pp. 27. London. 1849.

THE contents of this pamphlet have already appeared in our pages. The author has increased the utility of his "Contributions" by their republication in a separate form. They will be found to afford many useful practical hints to medical practitioners, by whom, we trust, they will be generally read.

Surgical Anatomy. By JOSEPH MACLISE, F.R.C.S.E. Fasciculi VI. and VII. London: Churchill.

IN these two parts Mr. MacLise presents us with coloured lithographic drawings—1. Of congenital and infantile inguinal hernia and hydrocele. 2. Of inguinal hernia in general. 3. The dissection of femoral hernia, its origin and progress, the seat of stricture, &c. 4. The surgical dissection of the femoral region. 5. The relative anatomy of the male pelvic organs. And, 6. the surgical dissection of the perineum. All these drawings are executed with anatomical correctness, and are well calculated to convey to the student of surgery a large amount of valuable instruction. The descriptive letterpress is appropriate. Another recommendation is, that it is the cheapest illustrated publication on surgical anatomy which has ever appeared.

The Metropolitan Interments Act; with Explanatory Notes, an Appendix, and Index. By H. H. OLIPHANT, of Trin. Col. Cam., B.A., and of the Inner Temple, Barrister-at-law. 8vo. pp. 100. Longmans. 1850.

THIS is a very convenient and useful publication at the present time. We commend it to all who wish to make themselves acquainted with an Act of Parliament which introduces one of the most important sanitary improvements of the age.

Deafness Practically Illustrated; being an Exposition of Original Views as to the Nature, Causes, and Treatment of Diseases of the Ear. By JAMES YEARSLEY, M.R.C.S.E., &c. &c. 3d edit. 8vo. pp. 244. London: Churchill; Highley. 1850.

WE need scarcely on the present occasion do more than reiterate the opinions which we expressed when reviewing the former edition of this work in the year 1847.

We may state that the author attributes nearly all diseases of the ear to morbid conditions of the mucous membranes of the throat, nose, and ear. Mr. Yearsley "holds all works on diseases of the ear to be of little value wherein reference to the mucous membrane is not imprinted on almost every page."

The work comprises many valuable

practical suggestions. It is addressed to the public as well as to the profession: the latter will doubtless prove the better judge of its merits.

A Plea of Humanity in Behalf of Medical Education. The Annual Address delivered before the New York State Medical Society, and the Members of the Legislature, at the Capitol, February 6th, 1849. By ALEXANDER H. STEVENS, M.D., President of the Society. Pamphlet. 8vo. pp. 47. New York.

In this eloquent and energetic address we have brought before us the claims of the profession of medicine in return for what it has done for the benefit of man in all aspects and states of society, and the high and honourable spirit in which it has been practised by its brightest ornaments, is ably set forth. On these considerations is grounded a powerful appeal for the encouragement of the best and most liberal education of its members. Though its illustrations belong for the most part to American history, this appeal may be read with interest in the parent country.

The Eleventh Annual Announcement of the Baltimore College of Dental Surgery. 1850.

DENTAL SURGERY would seem to be in a far more flourishing condition in the state of Baltimore than in England; for here we find a college with a provost, and professors of principles and practice of dental surgery; of special pathology and therapeutics; of anatomy and physiology, or of operative and mechanical dentistry; and a lecturer on dental chemistry!

It will excite no great surprise to find that the "faculty" of the Baltimore College confess that their classes are by no means so large as they had reason to expect.

Appended to the Report are two excellent Addresses, delivered to the "Gentlemen Graduates of the Baltimore College of Dental Surgery" by two of their professors: they contain very good injunctions on the regulation of conduct, and place before the "graduates" the highest motives for their guidance in practice.

Proceedings of Societies.

MEDICAL SOCIETY OF LONDON.

Oct. 19, 1850.

DR. J. R. BENNETT, PRESIDENT.

Valvular Disease of the Heart.

DR. R. H. SIMPLE, the author of this paper, commenced by observing that the diagnosis and pathology of diseases of the heart, although formerly wrapped in great obscurity, were now rendered remarkably exact and definite by the labours and researches of modern investigators. The healthy sounds were now referred to their true causes, and the morbid ones were accurately connected with their true pathological phenomena. But he considered that it might be a question, whether too much stress were not laid at present upon the stethoscopic indications in forming a prognosis, and whether or not too little regard were paid to the attendant circumstances and general health of the patient. He by no means denied the importance of cardiac diseases, especially of the diseases of the valves; but it was a curious circumstance, that notwithstanding both theory and experience taught us the extreme danger of such diseases, yet clinical investigation showed that very extensive disease of the cardiac valves *might* exist without seriously impairing the health or greatly abridging the usual term of human existence.

The author read the history of three cases which had occurred in his own practice: the first was that of a man who died at the age of seventy, without manifesting any of the usual severe symptoms of cardiac disease, although the stethoscopic indications showed very clearly extensive disease of the mitral and aortic valves; the second case was that of a lady, with whom the author was acquainted for more than ten years before her death, and who enjoyed during that time almost uninterrupted good health, and was actively and daily engaged in the superintendence of a large family: she died suddenly, at the age of seventy. In the third case, which was that of an infirmity patient, the author was acquainted with the existence of serious valvular disease for ten years before death: yet she suffered very few of the symptoms of cardiac disease, and died of pleuro-pneumonia, at the age of eighty-three. In all these cases post-mortem examinations were made, and most exten-

sive and serious cardiac lesions were discovered, consisting of an ossified condition of the aortic valves, rigidity of the mitral valves, and a dilated, ossified, and rigid condition of the great arteries. Dr. Semple considered, that whatever explanations might be offered to account for the comparative immunity of these patients from severe symptoms during life, yet the facts themselves were curious and instructive; and he thought he might appeal to practical observation to prove, that however important might be the diseases of the valves, and however valuable might be the information derived from the use of the stethoscope, these diseases were not so rapidly and invariably fatal as they were generally supposed to be. In forming a prognosis, however cautious and guarded it might be, facts such as he had brought before the notice of the Society should be held in view in forming an opinion.

LIVERPOOL MEDICAL AND PATHOLOGICAL SOCIETY.

Abscess of the Liver.

MR. PATERSON, after describing the general symptoms of acute hepatitis, proceeded to illustrate its various stages by the following cases:—

The danger in any way of deviating from proper diet during the progress and treatment of acute hepatitis need not be better exemplified than in the following case:—

The patient, though tolerably submissive to medical treatment in other points, was totally intractable on the subject of diet. Colonel P— had taken his passage to the Cape of Good Hope on board my ship. He was advised by his medical attendant to live on board from the time he came down from the country, where he had suffered from gastro-enteritis and hepatitis. On coming on board he was much exhausted and very pale, pulse weak, tongue white, belly tense, liver very hard, and he had a troublesome cough: the bowels were costive.

He was washed with hot water, while he remained in the recumbent position, and had an enema. In the course of the day he took ℥j. of calomel, with ʒss. of compound extract of colocynth, followed by ʒi. of compound powder of jalap, which produced only two stools. After a few hours' rest his pulse had risen slightly; and, though there was but little morbid heat, it was considered requisite to take 20 ounces of blood from the arm; and he had calomel.—Ext. Coloc. Ca., Pulv. Scam.

Ca., aa. ʒss., which were given in syrup, as he refused to take any more pills.

Oct. 23d.—He was purged freely, and felt better; the cough was moderated; the belly was generally softer; but the right lobe of the liver was hard, large, and tender if pressed. Pulse soft and natural.—℞ Calomel., Extract Colocynth. Comp., aa. ʒss. at 7 A.M.; Repet. V.S., ad ʒi. in the morning; 12 leeches to be applied to the liver at noon. At 4 P.M. he had only one scanty and light-coloured stool; after which he was seized with spasm in the belly, and some symptoms of cholera, attended with great anxiety, a soft pulse, and the tongue cool. He took calomel, ℥j.; Opii, gr. ii.; after which he became easy, and slept well all night. The leech-bites were bleeding freely next morning. The patient's tongue was warm, moist, and white. There was no pyrexia, and the apprehension of cholera had subsided. Leeches were applied to the belly daily for a week; and active purgatives with calomel were taken daily.

Nov. 13.—The belly had become less tumid, and softer; the tumour of the liver more distinct and circumscribed; the mouth was sore, and he felt weaker. The pain of the right side was subdued (at least, he did not acknowledge any pain on pressure); the enlargement of the liver remained, but it was softer.

After this a blister was applied to the right side, which was kept discharging by the savine oerate; a small number of leeches was applied daily to its surface; and liniment hydrarg. was rubbed over the belly and chest where the blister had not reached. The patient now became low-spirited, and said he was determined not to die of debility, and that, unless an unrestricted quantity of food were allowed, he had resolved to procure it. In this he was as good as his word; for, by the aid of his servants, he was well fed, and had no wish to conceal that fact. The first unfavourable symptom which arose from improper diet was a return of cough, then gradually increasing emaciation, and a sharpness of visage, followed by dysenteric symptoms, with blood in the stools. He lost all hope, and refused to take any remedial; the evacuations assumed the appearance of dark brown water, mixed with blood, and had a putrid odour: he was unable to rise to stool. Still the pulse did not exceed 86 when he was in the recumbent posture. He died on the 8th of December, 1842.

Dissection, nine hours after death.—Subject emaciated; universal adhesions of the right lung, apparently not recent. The liver was much enlarged, and of a pale drab colour; its structure was indurated; the convex surface of the right lobe was

extensively adherent at the space between the 7th and 8th ribs, and at that part contained a large abscess very near the surface; the margin of the right lobe adhered to the colon. There were numerous small ulcers in the colon and rectum. The mesenteric glands were enlarged, and the cellular texture at the root of the mesentery was consolidated. It is not common to find abscesses of the liver, as in this case, combined with the pale degeneration. Up to the 18th of November there appeared room to hope that the disease might have been cured, the rules of diet being attended to, and persistence in a correct treatment, so as to promote absorption.

In the only case where I have seen a superficial abscess of the liver exactly under the ligamentum latum, the patient was unable to lie on either side, but was obliged to rest on his back, with the shoulders very little raised. This patient was an emaciated European, a captain in the Engineers. He had resided about twenty years in India. He embarked on board my ship on our homeward passage, on the 9th of January, 1844. He was brought on board in his bed in the lowest state of misery and distress, having been ill with a purging for nine weeks, and voided much blood, part of which was in coagula. His pulse was 104, and weak: he was very feeble, and unable to rest on either side. There was a fulness of the epigastrium, inclining to the right side. Fluctuation was very distinctly marked. From the time he came on board, he urgently begged me to puncture the liver, which I at last reluctantly consented to do, owing to the weak state of the patient: his appetite kept very good. We had been nine days at sea, and he thought himself better; so I introduced a trocar into the most projecting part of the liver. There was a great discharge of purulent matter, fully two pints. The wound continued to discharge a considerable quantity for some time, my patient improving in health and strength daily. He was soon able to be carried upon deck; and what with nourishing diet, the sea breeze, and careful nursing, he improved rapidly; and in six weeks from the operation was well, and the wound closed. He continued well during the remainder of the voyage; had no pain in the liver; and died about two years after this time from inflammation of the brain.

A lady, of rather sallow and unhealthy aspect, after residing seven years in India, during which time she had suffered from dysentery, continued fever, and at last acute hepatitis, was recommended to England for change of climate. When she came on board she was pretty well, but slightly thinner than usual, she ate reasonably; but

soon after coming on board had some difficulty and oppression in breathing, and pain in the right side, which increased slowly. A few leeches were applied once, and mercury given until the mouth was sore. Eighteen days after embarking a troublesome cough came on, and on the 25th the pain in the right side grew worse, a slight degree of bloody expectoration appeared. On the 26th day, she suddenly experienced a sense of suffocation and extreme faintness, and coughed up about sixteen ounces of rather thick, viscid, puriform, grey-coloured matter. Hectic symptoms came on, and she became low and weak, but the pain at the right side ceased. Her appetite was pretty good, and she in a short time improved in health, and made a very slow and protracted recovery.

This lady remained three years in England, and quite recovered her health, and went to India to join her husband. I heard from her two months ago, and she was then well, and has had one fine healthy child since she returned to Bengal.

ACADEMY OF MEDICINE, PARIS.

Oct. 15, 1850.

Nephritic Amaurosis.

M. LIANDOUX transmitted a second memoir on this subject, with the following conclusions:—

1. Disorders of the sight are an almost constant symptom of Bright's disease of the kidney.
2. Nephritic amaurosis cannot be attributed to loss of power (*deterioration des forces*).
3. It often appears before other pathognomonic signs of the disease.
4. It appears, disappears, and returns, without following exactly the phases of the presence of albumen in the urine, and of the cedema.
5. Nephritic amaurosis must be regarded as a deranged state of the ganglionic nervous system.

Inhalation of Carbonic Acid in Phthisis, and a new Auscultatory Sign of the presence of latent Tubercles.

M. GRISOLLE read a report on a memoir by M. Le Goin, in which the author states his opinion that carbonic acid inhaled, freely mixed with air, produces a beneficial excitement in the lungs. The reporters do not concur in the views on the subject expressed by Dr. Le Goin.

The new auscultatory sign of latent tubercles which the author had observed was the occurrence of a crepitation heard with

the first inspiration immediately on waking, in the morning. M. Grisolle observed on this point that the phenomenon was purely physiological, the result of the less expansion of the air-cells during sleep, and that it could not be regarded as an indication of disease.

Etiology of Tuberculization.

M. PIERRE read an essay by M. Wanner, in which the author attributes the production of tubercle to the presence of lime in the soil of the district in which the patients reside, and stated that at Sologne, where the soil to a great depth consists entirely of silica and alumina, he had never met with a case of the disease.

SURGICAL SOCIETY OF PARIS.

Oct. 16, 1850.

Remarkable Gun-shot Wound.

M. HUGUIER was called to a patient who had received a gun-shot wound in the axilla under the following circumstances:—A man, 40 years of age, of a good constitution, had been shooting with a badly-made double-barrelled flint-lock fowling-piece. One of the barrels having been discharged, the imprudent sportsman proceeded to reload it, having puf in the powder, and rammed it down with a wooden rod; leaving the rod in the barrel, he was feeling in his pocket for the shot, when by some accident the same barrel was discharged into his axilla. The ram-rod traversed the axilla, shattering itself against the humerus into twenty-one pieces, without fracturing the bone. No hæmorrhage occurred. It was impossible to ascertain to what extent the articulation had been opened. The patient perfectly recovered. The twenty-one fragments of the ram-rod were exhibited by M. Huguier.

Cancer of the Tongue—Sudden Death from Oedema of the Glottis.

M. MOREL-LAVALLÉE presented a pathological specimen of the parts from a case in which cancer of the tongue terminated fatally by oedema of the glottis and larynx generally.

M. LENOIR exhibited a large calculus removed from Wharton's duct.

ACADEMY OF SCIENCES, PARIS.

Oct. 14, 1850.

Experimental Researches on the Woorara Poison.

M. BERNARD read the following as the results of experiments performed by him-

self and M. Pelouze on the woorara poison, prepared by the tribes inhabiting the districts of Upper Orinoco, Rio-Negro, and the Amazon:—

The woorara is a watery extract prepared from a plant of the *Strychnos* family. The poison acts instantaneously when introduced into the blood-vessels. A weak solution injected into the jugular veins of dogs caused sudden death, without producing cries or convulsive movements in the animal; the animal is, as it were, struck dead, and every trace of life vanishes as quickly as a flash of lightning. When introduced into a wound beneath the skin the poison acts more slowly, varying with the dose and the size or species of animal. *Cateris paribus* birds die most speedily, then mammifera, then reptiles. In every case the signs of poisoning are similar,—the animal will move about as usual for a brief interval, and then lie down and die without a cry or a struggle. Immediately after death the nerves of the animals are as inert and insensible to stimulation as if the animals had been long dead and cold. The blood is black, and does not readily coagulate nor redden on exposure to the air.

The poisonous effects of woorara present a close analogy with those of the bite of a viper, and, like that venom, is innocuous when taken into the digestive tube. That its properties are not then destroyed by digestion was made evident from the experiment of inserting some gastric juice into a wound, forty-eight hours after the poison had been taken into the stomach: the usual poisonous effects were manifested. Thus the strange spectacle was exhibited of an animal carrying in its stomach a substance which in no way interrupted digestion, but which, if taken from its stomach, is capable of inflicting death upon itself or any other animal.

This fact was explained by the discovery that the woorara is not absorbed from the alimentary mucous membrane. So long as the mucous membrane retains its integrity the woorara solution does not pass through the endosmometer. Other mucous membranes present the same results with the woorara: those of the bladder, nasal fossæ, and eyes, were experimented upon. The pulmonary mucous membrane presented the only exception. A few drops of the solution introduced into the air-passages produced the same morbid effects, and the same rapidity of death ensued as if it had been inserted beneath the skin. This exception is referred by M. Bernard to the circumstance that the mucous membrane of the lungs has not the same mucous secretion as is supplied to the other mucous membranes.

Caseine in the Blood of Women during Lactation.

MM. NATALIS GUILLLOT and FELIX LEBLANC announced that they had succeeded in separating caseine from the blood of women, and stated that they should take an early occasion of submitting their experimental researches.

Medical Intelligence.

THE USE OF CHLOROFORM BY THIEVES.

[THE following case, communicated by a correspondent, will show that some restriction on the sale of chloroform to the public is imperatively required.]

A gentleman named Mackintosh had retired to bed at an hotel in Kendal. He was awoke about twelve by a man attempting to suffocate him by means of a rag steeped in chloroform. Mr. Mackintosh, who is an elderly man, struggled desperately with his assailant; but, whether from the fumes of the chloroform, or the disadvantage at which he was taken by his midnight assailant, he felt himself fast fainting, when his cries of "Help! murder!" roused the house. When the landlord made his way into the room Mr. Mackintosh was almost powerless, and the assassin, or robber, was lying upon the bedding, which had fallen upon the floor in the scuffle, apparently sound asleep. On being roughly shaken, the latter professed that he had long been a sleep-walker, and appeared to be astonished to find himself where he was. A policeman was sent for, and the man taken into custody. A strong smell of chloroform was perceived by the parties who entered the room upon the alarm being given, and a bottle containing chloroform was found under Mr. Mackintosh's bed, and a similar bottle in the carpet-bag of the prisoner, who had been at the hotel since Saturday evening. The reverend gentleman's face bore strong marks of the pertinacity of his assailant, and, upon the landlord and the landlady entering the room, his night-dress was found to be covered with blood. There had been no key in the lock of his room, and he had placed a chair between the door and the bed previously to retiring to rest. This chair the people who entered the room on his cries being heard had to remove with some difficulty; so the probability is that the ruffian had secreted himself under the bed. The prisoner, who was brought up next day, it was proved, had retired to bed about half an hour before

Mr. Mackintosh. In the course of the evening he had taken occasion to tell the people of the house that he was a sleep-walker, and on one occasion he said he had walked four miles in his sleep. To the policeman who took him into custody he said he was a traveller, but refused to say for whom he travelled, or in what business. He was fully committed for trial.

. The *lex talionis* should be applied here. It would be only fair to give to this "Thug" in the disguise of an Englishman, such a dose of chloroform as would prevent him from making a similar attempt. Coroners and medical practitioners should be prepared for cases of this kind, since all persons have ready access to this powerful poison.

STATE OF THE PUBLIC HEALTH.

THE Quarterly Return of the Registrar-General announces that the mortality is much below the average, and the public health has never been so good since 1845 as in the present quarter. The rate of mortality is 1·901 per cent. per annum. At this rate, one in 211 persons living, died in three months. The chances of living through this quarter were 210 to 1; the average chances of living through three summer months (1849-50), for persons of all ages, being 192 to 1.

SALE OF POISONS IN FRANCE.

A GOVERNMENT decree of the 18th July had specified the following as substances to be kept and sold with especial precautions:—Hydrocyanic acid; the poisonous vegetable alkaloids, and their salts; arsenic and its preparations; belladonna, cantharides, chloroform, conium, cyanide of mercury, cyanide of potassium, digitalis, hyoscyamus, tartar emetic, nitrate of mercury, nicotine, opium, phosphorus, ergot of rye, stramonium, and corrosive sublimate.—*L'Union Médicale*.

X

A FRENCH SUMMARY OF THE LONDON MEDICAL SCHOOLS.

OUR contemporary the *Gazette Médicale*, in giving a summary of the London Medical Schools, places as third on the list the Lutheran Institute of Medicine and Surgery. The honour of the name is, by a trifling mistake, taken from John Hunter, and, curiously enough, assigned to Martin Luther! Of the 150 Professors which are said to be attached to the London schools, a selection is made of those who are best known to fame. Under the School of St. Bartholomew's, we find specially mentioned a M. Bunsen, whom our readers would hardly recognise as Dr. Burrows!

UNIVERSITY OF ST. ANDREWS.
MEDICAL EXAMINATION PAPERS, OCT. 1850.

First Examination.

To be translated into English:—

STATUS homo, qui et bene valet, et sua spontis est, nullis obligare se legibus debet; ne neque medico, neque intralipia egere. Hunc oportet varium habere vitæ genus: modo ruri esse, modo in urbe, sæpiusque in agro: navigare, venari, quiescere interdum, sed frequentius se exercere. Siquidem ignavia corpus hebetat, labor firmat; illa maturam senectutem, hic longam adolescentiam reddit. Prodest etiam interdum balneo, interdum aquis frigidis uti: modo ungi, modo id ipsum negligere: nullum cibi genus fugere, quo populus utatur: interdum in convietu esse, interdum ab eo se retrahere: modo plus justo, modo non amplius assumere: bis die potius, quam semel cibum capere, et semper quam plurimum, dummodo hunc concoquat. Sed ut hujus generis exercitationes ubique necessariæ sunt; sic athletici supervacui. Nam et intermissus propter civiles aliquas necessitates ordo exercitationis corpus affligit: et ea corpora, quæ morte eorum repleta sunt, celerrime et senescunt, et agrotant.

1. State the ultimate composition of Water, Muristic Acid, Oxalate of Lime, and Acetate of Potash.

2. What are the compounds of Chlorine with Oxygen?

3. Describe the ordinary tests for Arsenious Acid.

4. What are the usual methods of preparing Calomel, Tartarate of Potash, Tartar Emetic, and Prussic Acid?

5. Mention the most important preparations of Iron, the cases in which they are specially applicable, and the mode and dose in which they should be given.

6. How do Digitalis and Colchicum act, when given in ordinary and in poisonous doses? In what diseases, and in what forms and doses, may they be administered? Write a Latin prescription (without using abbreviations) for a diuretic mixture containing Digitalis and Squills.

7. What is Ergot? Mention its most important therapeutic uses, and the best modes of administering it?

Second Examination.

1. Describe the chemical and microscopical characters of healthy Venous Blood. How are the Corpuscles of Blood, Pus, and Milk to be distinguished from one another?

2. Describe the structure of the Lungs.

3. Mention the different parts into which the Small Intestine is divided, and describe its general structure. How can we

determine to what division the isolated portion of gut belongs?

4. Describe the course and the most important communications of the Facial Nerve. What is its function? Mention the most striking effects resulting from its paralysis.

5. Describe the course of the Spermatie Cord, and the parts which enter into its formation.

Third Examination.

1. What are the differences between Endemic and Epidemic Diseases? What are the most probable hypotheses regarding the causes of Epidemic Diseases?

2. What are the physical signs and general symptoms of the different stages of Pulmonary Phthisis? With what diseases is it liable to be confounded? Give a sketch of the treatment to be adopted, (1.) to prevent the disease when it is likely to occur, (2.) to arrest its progress when it is incipient or limited in extent, and (3.) to alleviate the most distressing symptoms in hopeless cases.

3. Give the symptoms, diagnosis, and treatment of Carcinoma of the stomach. Which variety of Carcinoma most commonly affects this organ?

4. Describe the Oxalic Diathesis, and the proper treatment of it. In what form or forms does Oxalate of Lime appear in the urine, and how do you distinguish it from Uric Acid, and from Ammonio-Magnesian Phosphate?

5. Give the distinguishing characters, causes, and treatment of Urticaria, Prurigo, and Psoriasis.

6. What is understood by Caries? Mention its causes, and give a brief outline of the treatment to be pursued.

7. Give the symptoms and treatment of Dissection Wounds.

8. Describe the causes and treatment of Tedium Labour.

List of Gentlemen who had the Degree of Doctor of Medicine conferred upon them, Oct. 18th, 1850.

J. Ainsworth, M.R.C.S.I., Antrim, Ireland.
A. T. Brett, M.R.C.S.E., L.A.C., Surrey.
E. B. Dorman, M.R.C.S.E., L.A.C., Kin-sale, Ireland.
A. Eves, F.R.C.S.E., L.A.C., Cheltenham.
J. Furse, M.R.C.S.E., L.A.C., Devonshire.
H. C. Rooda, M.R.C.S.E., London.
W. H. Woods, A.B., Trinity College, Dub.-
Dublin.

RENCH MEDICAL JOURNALISM AND THE
LAW OF THE PRESS.

Is that glorious land of liberty, equality, and fraternity,—France,—it is now the law that no leading article, or any article

whatever, can be inserted in a *medical* periodical without the name of the author being attached to it, under a heavy penalty of fine and imprisonment. Our contemporaries are politely indignant at this tyrannous exercise of the censorship; but, as it is one of the results of "*vole by bullet*," they are compelled to submit to it.

PREVENTION OF BURIAL CLUB MURDERS.

In the new Friendly Societies' Act there is a provision respecting burial clubs. In future, the money to be paid on the death of a child under ten years old must be under £8, and can only be paid to the undertaker for the actual expenses incurred. No money must be paid on the death of a husband, wife, or child enrolled, except on production of a certificate from a physician, surgeon, apothecary, or seer, according to a form annexed to the Act, that the party had not been deprived of life by any person interested in obtaining the burial money. If any officer of a society pay the money without such a certificate, he will be liable to a penalty of £10, one half of which will go to the informer.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN IN LONDON AND ITS VICINITY.

A HALF-YEARLY General Court of this Society was held on Wednesday, Oct. 23, at the Gray's Inn Coffee-house, Holborn, Sir Charles Mansfield Clarke, Bart., M.D., the President, in the chair.

The annual ballot for the election of the Court of Directors took place; and, in the room of the six senior directors who retire in rotation, the following gentlemen were elected—viz., Dr. Cape, Dr. A. J. Sutherland, Messrs. Beaman, Lane, Clifton, and Bird.

Thanks were voted to the auditors, and to the acting treasurer, Dr. W. Merriman.

The President announced that, in consequence of the lamented death of the patron, he had, in compliance with the wish of the Court of Directors, written a letter of condolence to H.R.H. the Duchess of Cambridge. This letter, with its answer, was read, and contained a judicious allusion to the merits of the medical profession.

It was resolved that H.R.H. the present Duke of Cambridge be respectfully invited to become the patron of the Society.

At the conclusion of business, the President very feelingly called attention to the fact that the Society's grants to widows and orphans of deceased members, amounting to £780 for the current half-year, are derived almost entirely from the members of the Society themselves, and not from the public, who were too apt to forget the services of the medical profession when not actually needed.

OBITUARY.

ON Friday, the 25th ult., at the residence of his father, at Enfield, Middlesex, Dammett Asbury, Esq., M.R.C.S., and L.S.A. (1848), aged 23, after three days' illness, from the poisonous effects of a wound received at a post-mortem examination.

On the 27th ult., at Ipswich, John Ransom, Esq., surgeon, aged 33.

Selections from Journals.

EXAMINATION OF THE DEAD FOR JUDICIAL PURPOSES. DEATH BY DROWNING. BY DR. CASPER.

THERE is at the present time scarcely any greater desideratum in medical jurisprudence, than a sure criterion for the determination of the fact, whether a person has been drowned, i. e., has died in the water. The best authors differ widely in their decision of the question. How often is it disputed whether a person found drowned has died of apoplexy or strangulation; whether the frothy mucus found in the trachea be a sign of death by suffocation; what is the true value of the *cutis asserina*, the fluidity of the blood, and many other uncertain signs. From the examination of a great number of bodies of persons drowned, Dr. Casper comes to the conclusion that no certain or constant signs are met with in death from drowning.

It may generally be admitted that a person has perished in the water, if no trace of apoplexy, or disease of the lungs, heart, or brain be present; if the blood be dark and fluid, the mucous membrane of the air-passages injected of a light red colour, the larynx and trachea containing more or less of a sanguineous mucus; if on particular parts of the body, more particularly on the shoulders and forearms, the *cutis asserina* be very distinct; and lastly, if, in addition to all these signs, there be added the negative evidence of the signs of any other mode of death. Putrefaction, however, often vitiates all the proofs afforded by the state of the body. Both the condition of the blood itself, and of the internal organs, undergoes great change, and the state of the skin no longer affords any indication. Dr. Casper's predecessor, Dr. Wagner, observed the *cutis asserina* formed in several instances while the body was yet warm. This phenomenon is rarely met in men of dense strong fibre—as labourers, who during life have not a very delicate skin, and in whom after death the integuments exhibit a carnosous state. Where putrefaction has proceeded to the elevation of the

cuticle in vesicles, *cute anserina* cannot be present. In nearly all putrified bodies, the proof of drowning can only be established on negative evidence.

The following cases are related by Dr. Casper, in illustration of his observations:—

The dead body of a child, two years of age, was found in the water. There was slight congestion of the brain. No water was found in the trachea or bronchi, although the glottis was open; the lungs were exsanguineous, and the cavities of the heart were absolutely empty: there were no indications of either apoplexy or suffocation. The blood was of a light red colour, and unusually fluid. The stomach was filled with water, in which floated fragments of meat. No signs of any other mode of death could be discovered, and therefore from their absence, rather than from any positive proof afforded by the examination, the probability of death by drowning was admitted in this instance. The unusual circumstance of the stomach being filled with water was afterwards explained. The child had been playing on a hot summer's day at the water's edge, and being thirsty the nurse had given it a large draught of water, which was drunk with eagerness. The nurse left the child for a short time, and on her return found that the infant had fallen into the water and was drowned.

The following case is here introduced chiefly for its singularity:—

A servant girl disappeared on the 21st of March, 1841. It was reported that she was pregnant, and her disappearance was considered not to be accidental. All search proved unsuccessful, and the case was almost forgotten, when, in December of the same year, nine months afterwards, the cesspool of the house being emptied, the workmen found a putrid human body therein. It was immediately suspected to be the body of the missing servant-girl, and a judicial inspection was forthwith ordered. Dr. Casper states that he had never seen a corpse in a higher degree of putrefaction, as might be supposed after nine months' maceration in human excrement. Even the hardened attendant of the dissecting-room experienced nausea from the indescribable stench which this corpse occasioned.

The skull, the lower jaw, the lower extremities, were for the most part denuded of their soft coverings; the ligaments of the joints were partly exposed; the external sexual organs were not recognisable: what soft parts remained were converted into greyish black shreds. To the question, put officially, whether it was not possible to ascertain the fact of pregnancy in this case, Dr. Casper answered affirmatively, provided that the rudiments of a fetus were discovered

in the uterus. The abdomen was opened for this purpose. The muscles were found converted into adipocere, and the intestines were changed into a greasy mass, in which it was impossible to distinguish the parts or form. The uterus was of a bright red colour, hard to the feel and to the knife, of the virgin size, its form perfectly distinct and normal, its cavity empty, and corresponding to the virgin condition.

Although in this case nothing positive could be stated with reference to the cause of death, it could be affirmed in court that at the time of death the person was not pregnant, thereby removing the unjust suspicions which had been attached to her memory, and to the character of another respectable person, since the girl's disappearance.—*Casper's Wechenschrift*. x

AVERAGE DURATION OF LIFE IN THE NEW WORLD.

THE recent report of this Board of Health of New Orleans contains the following summary:—

The average life in no country reaches threescore years and ten, announced in Scripture as the period for the duration of the life of man. The average age at death in the northern cities—doubtless owing in a great measure to the large mortality in infantile life—is from 19 years 9 months to 20 years 3 months; and in some of the cemeteries where destitute foreigners from the crowded parts of the city of Boston are buried, it is reduced to 13.49. In the south, where it is so much more favourable to infantile life, the average age is much greater. In Charleston the average age at death is near 36 years. In Vera Cruz 24.6, and in the city of Mexico 27.7; while in the city of New Orleans, the average age at death for the last year was 26.69; and in a series of the years, the aggregate of all the cemeteries was 22 years 6 months 3 days.

Of all countries on record, the rural parts of England and Massachusetts are probably most favoured with respect to infantile life; and yet in Massachusetts 40 per cent., and in England 47 per cent., die while they are going through the process of development, and before they enter upon self-sustaining life, in their 16th year. In New Orleans we have not the data to institute an exact comparison at these ages, but very near it; and we find that here only 36.98 per cent. die under 20. In this city data of all kinds are defective; we have, nevertheless, been able to construct a chart, to show the real value of life here at successive ages, and at different periods of the year. It is too lengthy for this report. We may, however, state that it shows the extremely mild character of the climate at

all periods of life: under 20, and above 50, and during all months of the year, and that the chief fatality occurs from 20 to 40 (the ages of the immigrating population), and the period, the latter part of summer. Notwithstanding all this, the following statement shows that we have a larger proportionate population at the *productive age*, that is from 20 to 50, than the most favoured parts of the world: viz. in every 10,000 in the United States, there are 3,708 10,000 in Louisiana, " 3,753 10,000 in England and Wales, " 4,028

While there are in every 10,000 in New Orleans, " 4,924

From all the information we can procure, it is satisfactorily demonstrated, that in countries where from climate, position, and refinement, a very small part of the population reach the age of their natural destiny, they approach it nearer, in proportion as they obey the laws which are adapted to the guidance of life: here, notwithstanding our deficiencies in many respects, sufficient is ascertained to hope for as near an approximation to the primeval age as anywhere; and reference to the table showing the number of the dead above 80 and 100—11.58 per cent. of the first, and 2.26 of the second—buried at the Catholic cemetery; the chief cemetery of the ancient Creole population of the city—will satisfactorily prove the fact.—*American Journal of the Medical Sciences* for July, 1850.

Lectures.

CLINICAL LECTURE

ON A CASE OF

DISEASED BRAIN, CAUSING
DOUBLE APOPLEXY,

(Delivered at King's College Hospital),

By R. B. TODD, M.D. F.R.S.

Physician to the Hospital.

(Reported by M. H. SALYER, B.A., Dem. Anst.
K.C.L.)

LECTURE XIII.

I PROPOSE to-day to offer you some remarks on the second case which was to have formed part of the subject of my last lecture. It is a case of the same nature as that on which I last commented, and it serves to illustrate the mode in which white softening of the brain is apt to take place, and the way in which that disease favours the production of apoplexy. We are fortunate in having a very full account of the case, taken with very great precision, by my clinical clerk, Mr. Vaux.

The subject of this case was named George Regan, his age was 59 (vol. xxiv.), he was admitted into Sutherland ward 20th of January, 1849. He was a glass-cutter by trade, and had lived well all his life; he, however, called himself temperate, but admitted that he had been in the habit of drinking a good deal of beer and spirits.

This man seems to have suffered long from what he calls rheumatism, but which from his habits and his age I should think was rather of the nature of gout; he had, however, no regular fit of the gout, but complained of pains in various situations, and for these he was for some time an out-patient at the hospital.

About two years ago, he was seized suddenly while at work, at nine o'clock in the morning, with a feeling of stupor: as he happened to be working at home at the time, he laid down on his bed, hoping to sleep it off by dinner-time, but when he attempted to get up he fell, and found that he had lost the use of his right side; he then became comatose, and so continued for some days. Whilst in this state of insensibility he was taken to a neighbouring hospital, where he remained for two or three months, and at the end of that time in some degree recovered from his attack, but not so as to enable him to work as he had done before his illness.

During last October he had a second

attack, of the same kind as the first, but less severe; the limbs were paralyzed, as before, on the right side; he remained a few days in bed, and recovered in some degree the use of the arm and leg, but he has never been able to work since.

On Christmas day last, at nine o'clock in the morning, before he was up, he had a third attack; on this occasion he was delirious for a short time, and afterwards became insensible, but he recovered his consciousness in the evening.

This third attack brought on increase of the paralysis on the right side, so that on this occasion not only was the motor power affected, but the sensibility likewise. This latter function was so far affected, that he could not pick up small objects, and he would frequently let fall things which he meant to retain in his hand, and he staggered when he attempted to walk. It was more than three weeks after the attack when he was admitted, and the paralytic state had not improved; on the contrary, he thought it worse. His condition on admission was as follows: there was imperfect palsy of the right side, as shown by slight ptosis of the right upper eye-lid, and a slight hanging of the cheek, the features being slightly drawn to the left side. He would protrude his tongue straight, but his articulation seemed somewhat difficult. In walking he slightly dragged the right leg; the grasp of the right hand was moderately firm, but not so firm as that of the left; the muscles of the right leg and arm were flaccid, and less nourished than on the left side. The impulse of the heart was very strong, and a mitral systolic bellows sound could be distinctly heard.

For some days after his admission he suffered very much from constipated bowels, which it required the strongest purgatives to overcome. He then began to complain of heaviness of the head, a disposition in his thoughts to wander, and a difficulty in collecting them. These symptoms appeared to me to portend the approach of another attack, such as he had on three former occasions. His remarkably sallow complexion and general leucophlegmatic appearance led me to suspect the existence of renal disease, resulting from that particular form of kidney—small and atrophied—which so frequently accompanies a gouty condition. This opinion was confirmed by the characters of the urine, which was pale, of low specific gravity, and slightly but distinctly albuminous. With this view, and imagining that the uneliminated urea might be contaminating the blood, and affecting the brain, I ordered him to be freely blistered at the back of the neck. This seems to have somewhat relieved him, for the next day he was reported to feel, and

ther easier as to his head, and to have more power over his thoughts. At nine o'clock, however, on the following morning, the house-physician, Mr. Arncliffe, was called to him, in consequence of his having been suddenly seized with a fit; he found him completely paralyzed on the left side, both as to sensibility and voluntary motion; his left eye squinted, and was twisted downwards and inwards; at every expiration his left cheek puffed out from want of power of the buccinator; the right leg and arm moved when pricked, the left not; his breathing became louder and more stertorous, his coma deeper, and at last he died.

There was in the attacks to which this patient was subject a curious combination of the epileptic and apoplectic, the one following upon the other. At the foundation of them, no doubt, was the diseased state of kidney. The first attack of sudden stupor was probably a slight epileptic seizure, the effect of which was a disturbance in the circulation in the brain, and the giving way of some small vessels—a slight apoplexy, with compression and rupture of fibres, and consequent paralysis.

Whilst the one or two small clots which had been effused on this occasion were undergoing absorption, and some attempt at reparation was taking place, he had another seizure of the epileptic kind,—a further disturbance of the circulation and nutrition of the brain on the same side, probably in the corpus striatum, or the fibres which pass from it to the hemisphere. But as the paralytic state appears to have been only slightly increased, and as the coma was of short duration, it is not likely that any effusion of blood took place on this occasion.

The epileptic character of the third attack was manifested in the delirium with which it was ushered in, and which ended in coma. There was a decidedly increased paralysis after this attack; but inasmuch as quite as much paralysis is apt to follow the simple epileptic seizure, it by no means follows that any effusion of blood took place, although it is probable that such must have been the case, from the fact that the palsy showed no signs of improvement, as is generally the case with the epileptic palsy. As this attack occurred at a time when Christmas festivities are more or less prevalent with all ranks and classes, it is very likely that the immediate exciting cause of the attack was due to over indulgence of some kind.

The fourth attack had in its premonitory signs all the characters of a threatening epileptic paroxysm; and knowing, as we did, the existence of renal disease, we were prepared for such an attack. The

epileptic coma, however, soon passed into the profounder coma of a compressed brain; and as a new hemiplegic paralysis of a very complete kind showed itself on the left side instead of the right; it was easy to infer that a new and extensive apoplectic effusion must have taken place on the right side of the brain.

Assuming that the first three attacks were epileptic, followed by an apoplectic effusion, and that this effusion was due to a weakened condition of the arterial coats as the result of disease, it was quite consonant with experience to attribute the fourth attack to a similar cause, and to infer that arteries similarly diseased had given way on the left side of the brain. Most cases of rupture of vessels in the brain at the age of this patient take place from disease of the arteries; and it is very common, as was first pointed out by Bistot, for the arteries of the brain to be affected in a symmetrical manner—i. e. corresponding arteries of opposite sides will be similarly diseased, and to nearly the same extent. In this way disease had been, for some time, making progress in this man's brain symmetrically; there was first palsy of the right side, and then a similar condition of the left; and this simple fact of symmetry pointed to the arterial system as the seat of disease, and therefore to its usual result, apoplexy.

On opening the patient we found there was a double apoplexy corresponding to the double paralysis—one of long standing, and one recent—the first on the left hand, the other on the right. The original hemorrhage affected the corpus striatum and optic thalamus on the left side; and it was evident that the hemorrhage on this side did not take place at once, but on two occasions, at least. The substance of the corpus striatum had evidently been the seat of the older effusion. It exhibited on section several bloody clots, and that peculiar yellow discolouration which always succeeds to a hemorrhage. The more recent effusion was a clot which had formed quite on the surface of the optic thalamus, extending likewise to the corpus striatum, and lodged in a depression on the surface of those bodies. We had thus an explanation of the cause of the original paralysis of the left side; and its imperfect nature was plainly due to the fact, that there was but little destruction of the corpus striatum, and that the compression of the later clot affected chiefly the optic thalamus, and but slightly the corpus striatum.

But the apoplectic effusion on the right side was much more extensive; it involved parts corresponding to those affected in the first seizure, but to a much greater extent; and the brain substance

was more completely torn up and destroyed. The clot was very large, and it entirely filled the right lateral ventricle, breaking through its roof, and tearing up the white substance of the cerebral hemisphere; it likewise tore up the corpus striatum, optic thalamus, and the septum lucidum, all which parts were completely swept away. This remarkable destruction was no doubt owing to a previous diseased state of the brain. I mentioned to you in my last lecture that it is very common for apoplectic effusions to be preceded by white softening; and when the softening has got to a certain extent, the brain substance is no longer an adequate support to the vessels, which, themselves more or less enfeebled by disease, give way, not in one point only, but in many, and the abundant effusion plunges up the softened matter, quite destroys it, and takes its place: all this was the case in the present instance. The arteries of the brain were very generally diseased on both sides, and exhibited that symmetry to which I have alluded.

It is probable that the first part of our patient's last attack—the disposition of his thoughts to go wool-gathering—took place in connexion with the softening; while the final catastrophe—the apoplexy and death—resulted from the hæmorrhage to which that softening, coupled with the diseased condition of the arteries, inevitably led.

We found, likewise, as had been anticipated, a very diseased state of the kidneys: they were very contracted, the cortical substance much wasted, fissured, and granulated on its surface, the tubular substance healthy, and the capsule thickened. This condition of kidney, formerly described as the third stage of Bright's disease, is, in reality, a chronic degeneration or wasting of the kidneys, due to a deranged and damaged nutrition, for which I should be glad to find some other name than chronic nephritis: I have called it *gouty kidney*; and in this and many other cases this name is very appropriate. But it occurs in cases where there is no evidence of gout. The result of the disease is to render the kidneys imperfect excretories for the elimination of the urea, and other elements of the urine, which accumulate in the blood, and give rise to various morbid changes throughout the body, and are especially mischievous to the functions of the brain.

The heart and the arterial system were likewise extensively diseased. In the coats of the arteries were very numerous deposits of atheromatous matter. The heart was much dilated and hypertrophied, especially as regards the left ventricle. The fibrous basis of the valves was extensively thickened, apparently by some deposit, which

rendered it opaque; and impaired its flexibility; and, as is generally the case in this particular form of disease, all the valves were altered in this way; those of the right side, however, being much less diseased than those of the left. The semilunar valves of the arteries, especially of the aorta, had the fibrous festoons at their bases much thickened, the curtain of the valve being very little affected, and its function, therefore, but little impaired; and the cordæ tendinæ of the mitral valve were much thickened, and somewhat shortened, and the curtains of the valve also thickened. Similar changes had taken place in the tricuspid valve and its tendinous cords, but to a much less extent.

Taking, then, a general retrospect of this case, we find there is quite enough to account for all we have seen. The sequence of the events may be thus described:—First, the man gets into a general gouty condition, and the elimination of this morbid material gives rise to an irritation of the kidney, which at length assumes the form of gouty kidney, or, if you will, chronic nephritis; and this chronic nephritis incapacitating the kidney for the perfect discharge of its function is the cause of all the subsequent maladies: the blood becomes contaminated, deposits take place in the tissues of the heart's valves, in the large arteries, and in those of the brain; the diseased arteries of the brain become insufficient channels of supply; white softening is the consequence, and the unsupported and unhealthy arteries at length burst; and thus all the circumstances, from first to last, fall in regular order as cause and effect.

The deposits in the arteries produce a two-fold influence upon the circulation—by roughening the inner surface of the arterial channels they create a certain amount of direct obstacle to the flow of blood from the ventricle; and by diminishing, or nearly destroying, the elasticity of the arterial walls, they destroy one of the most important forces by which the circulation is carried on in the arterial system. Thus the arteries, from being elastic yielding channels, with perfectly smooth inner surfaces, are changed into resisting inert tubes, with rough inner surfaces. It is plain, then, that, under these circumstances, the heart has to encounter great obstacles, and to do a great deal more work than when the arteries are in their normal state. Hence the dilatation caused by the obstacle to the free flow of the blood; and the hypertrophy, by the greater exercise and effort of the muscle of the heart. The increase of force is merely remedial, to meet the increase of obstacle, and is one of those beautiful instances of self-adaptation.

to change of circumstances with which the animal organism, especially the muscular system, so much abounds.

As these deposits go on they impair the materials of the arteries of the brain; the degenerated walls of these vessels possess less strength, and are less able to support their contents. There is no undue determination of blood to the brain, but the reverse, for the blood that goes to the head has, in the erect posture, to be pumped up against the force of gravity; and, therefore, any obstacle in the course of the arteries would be more felt in this direction than in any other. It is a common notion that the hypertrophy of the heart gives rise to the apoplexy, by sending the blood with an undue impulse to the head; but for the correction of this error we need only remember that the additional force is merely such as is necessary for the exigencies of the circulation, and such as shall preserve the force of the blood's current as near as possible to the normal point, in spite of the existing obstruction. The actual force with which the blood circulates in the morbid arteries is most probably less rather than greater than in health. The apoplexy is, in fact, due to the diseased state of the arteries, which renders their walls an inadequate support to their contents, and to the diseased state of brain, which imperfectly supports the arteries.

A vast number of the cases of apoplexy which occur about the period of life of our patient, or after the age of 50, are of this kind—a fact that has an obvious and an important bearing upon the question of treatment.

There is a practice, unfortunately too common, but which, I think, is every day becoming less common—namely, that of following an attack of apoplexy by depletive measures, very much as a matter of course. However applicable such a mode of treatment may be to strong, young, hale, and plethoric subjects, I presume no one will say that it is very well adapted to patients who have passed the meridian of life, and whose blood and whose tissues are more or less contaminated by gouty matters, and with whom a morbid state of the arteries of the brain has already greatly weakened the nutrition of that organ. The case, indeed, which I have just detailed to you, is one of many which proclaim loudly that a depletory system ought not to be pursued indiscriminately, or even generally, in apoplectic cases.

With reference to this question of depletion in apoplexy, I would refer you to an interesting and very useful work by Mr. Copeman, in which he has collected, from a great variety of sources, a large

number of cases which presented the symptoms of apoplexy. Of 155 cases in which the treatment was specified, 129 were bled, and only 26 were not. Of the 129 who were bled 51 recovered, and 78 died—the cures being 1 in 2½, the deaths 1 in 1½. Of the 26 who were not bled 18 were cured, and 8 died, the proportion of cures being 1 in 1½, and of deaths 1 in 3¼. Eighty-five of the cases were bled generally and copiously, and of these only 28 recovered, and 57 died—in other words, two in every three cases terminated fatally. I am quite aware that the small number of cases not bled casts some doubt on the validity of the conclusion to be drawn from the comparison of the results of the treatment. But the fact that considerably more than half of those treated on the antiphlogistic plan died (and we owe much to the industry of Mr. Copeman for bringing it out), is a highly significant one, and should arrest attention.

I think I have now said enough to convince you that the treatment of patients with apoplectic symptoms must not be regarded as a matter of routine, but as a question of grave import, and which demands the most anxious consideration of the practitioner. Let me add, that it sometimes requires the exercise of no small courage and self-possession to resist adopting that practice; for the popular feeling, led by the prevalent medical practice, is entirely in favour of it, and would readily condemn a practitioner as guilty of the death of his patient who suffered him to die unbled. It is a far more daring and courageous thing to open a vein on the spot, and in the presence of a number of anxious friends, than to adopt less showy, and apparently less active, measures.

But, indeed, you need not be inactive, even if you decide against adopting the plan of bleeding. Having placed your patient in an easy position, in which no excitement of muscular action is likely to take place (for you must bear in mind that reflex actions may often be readily excited in these apoplectic cases), you should immediately direct your attention to the state of the stomach and intestinal canal. Sometimes in these cases the stomach is overloaded, or the bowels are confined, and the administration of a little purgative medicine will often provoke a moderate sickness, which unloads the former. Nor can there be any objection to adopting measures to clear out the bowels, either by an active purgative administered by the mouth, or by stimulating and purgative enema.

If, upon full inquiry into all the particulars of the case, you find that your patient is of full plethoric habit, with too much blood in his body, and with a suffi-

clearly strong heart, you may bleed him with every chance of success; but if he has been of intemperate habits, is labouring under organic disease of the heart and arteries, is of gouty or rheumatic constitution, then, whatever popular or medical custom may say, my advice to you is, hesitate much before you deplete by bleeding.

The objects which it is proposed to gain by bleeding are a diminution of the cerebral congestion, and the stoppage of the hæmorrhage into the brain; and where it is quite clear that cerebral congestion does exist, and that that congestion causes the cerebral hæmorrhage, this is clearly a rational practice. But you must bear in mind that in a large number of the cases—probably the majority—there is in reality no cerebral congestion, and that the hæmorrhage is of a kind not likely to be stopped by taking away blood—by establishing another hæmorrhage elsewhere.

On the whole, then, I think that the results of experience denote that the majority of cases of apoplexy are best treated by purging, shaving the head and keeping it cool—perhaps blistering, and that bleeding is rarely applicable, except to the young, vigorous, strong, and plethoric.

QUARANTINE PRECAUTIONS AGAINST CHOLERA IN SWEDEN.

THE system of quarantine against the cholera, abandoned as useless in almost every other state of Europe, prevails in Sweden in its utmost rigour. It is not only enforced against all persons entering the country from abroad, but the several provinces are closed against each other. If the disease appears in any place, it is cut off from all communication with the neighbouring towns. For the protection of Stockholm a quarantine station is established on the Gotha-Elf, under the command of a marine officer. In the interior the isolating system was put in force before it was adopted in the capital. In all the larger towns a guard at the gates sends back all travellers who cannot prove that they have not visited any infected place for ten days. In Ostgothland it is proposed to establish a military cordon along the canal. At Södertelge a ship of war is placed that compels all vessels as they arrive to anchor in the quarantine station. Vessels from the Hjelmar and Mälaree are detained at Långholm, and examined. In the North of Sweden these regulations are only enforced against persons; but in the town of Lund they are extended to goods if they are imported through Malmö.

Original Communications.

ON THE USE AND ABUSE OF ALCOHOLIC LIQUORS.

By THOMAS MAYO, F.R.S.

Fellow of the Royal College of Physicians.

Καλεστων το μετρον ειπεν.

In the "Outlines of Medical Proof" * I have endeavoured to illustrate, from the work of a most distinguished philosopher, defects incidental to the application of hypothesis, through a forced accommodation of such hypothesis to the series of phenomena which it professes to explain. But we need not wander to Giessen in search of evidence to the reality and importance of these defects. We are met by it in our English medical literature, and we find it in works from which we should feel most anxious to exclude such defects; works, namely, which treat of medical or hygienic subjects in their most practical relation to the wants and habits of society. Let us take up the prize essay of Dr. Carpenter, "On the Use and Abuse of Alcoholic Liquors in Health and Disease." The physiological or pathological objects pursued in this work are two-fold—very mixed up, indeed, and confounded in his mode of treating the subject, but capable of being estimated separately; namely, to point out and illustrate the fearful mischievousness of intemperance; and again to point out, that the "Moderate habitual use of alcoholic liquors is not beneficial to the healthy human system;" in the course of which proof he makes his reader fully aware, that he conceives himself also to have succeeded in proving this habitual moderate use to be probably *prejudicial* to the human system.

My purpose being practical, and the mischievousness of intemperance being unquestionable, and admitted at all hands, I will limit my remarks to the last mentioned object of Dr. Carpenter's proof, so far as I can disentangle it from the subject of intemperance and excess, from which I regret to say the author is

* Outlines of Medical Proof, revised and corrected.

at no pains to keep it philosophically separate. It is, indeed, a part of the unintentional policy of the prize essay, so to manage the lights which it throws upon intemperance, that they shall glance off, and shed an ominous colouring upon moderation.

"What," says Dr. Carpenter, "are the effects, corporeal and mental, of alcoholic liquors, on the healthy human system?" This question, in the mode in which it is put, is unreserved, and applies alike to excess and moderation. He answered it first, physiologically,—that is, in relation to the influence of alcohol upon the physical, chemical, and vital properties of the animal tissues and fluids,—then, pathologically.

With respect to the *physiological* answer, it runs thus:—"Corrugation of tissues; coagulation of albumen; impairment of solidifiability of fibrine; irritating action on living textures; temporary exaltation of nervous powers; change in red corpuscles. These propositions are unquestionably the result of a process of inductive inquiry, and are captivating as such; but I have vainly endeavoured to find out what bearing they may have on the moderate habitual use of alcoholic stimulants? With respect to Dr. Carpenter's *pathological* answers, in the remaining sections of the 1st Chapter, they place before the reader a string of maladies all usually imputed to excess, and not brought home by him to the moderate use of alcoholic liquors.

Now I can conceive some one, in his anxiety to obtain information on this very important subject, addressing Dr. Carpenter in the following terms:—"You have laid down, sir, before us five physiological inductions or results of an inductive process. What are your deductions from them? Do they infer mischievous results from the excessive use of alcoholic liquors? Of these every one has long since been aware;—or from their moderate use? But on this latter point we have your own affirmation, in your republished article from the Quarterly Review, that "if the whole world be really temperate in the use of fermented liquors, there would be no need of total abstinence societies." We must, indeed, conceive your deductions, if they apply only to excess, to amount to a truism, which does not reach the object which you evidently have in view in your prize essay,—namely, to discou-

rage the use of these stimulants in any quantity among persons in a healthy state; and yet we must consider, on the strength of the above quotation, that you are not yourself convinced of the soundness of this view, but that you support it rhetorically; and "because," as you say in the same article, "sad experience has shewn, that a large portion of mankind cannot be temperate in the use of fermented liquors; and that nothing short of total abstinence can prevent the continuance, in the rising generation, of the terrible evils which we have at present to deplore, because experience has further shewn that the reformation of those who are already habitually intemperate cannot be accomplished by any means short of entire abstinence from fermented liquors; and because experience has also proved that this reformation cannot be carried to its required extent without the moral influence of the educated classes. Such influence, you say, can only be afforded by *example*." Thus, sir, in your conscientious anxiety to make out a case for the total abstinence societies, you defend it on grounds which appear to us contradictory."

Leaving Dr. Carpenter in the above dilemma in regard to his *general* description of the subject, I may observe that the same method of *physiological* deduction is to be found in other parts of his essay, in which he more particularly discusses the question how far a moderate use of alcoholic liquors is expedient or prejudicial in our normal state. Thus, in testing the capability of alcohol to perform its functions as a heat-producing material, we are told that "Dr. Prout and Vierdot are both of opinion that alcohol, and all liquors containing it, have the remarkable power of diminishing the quantity of carbonic acid gas in the expired air." But Liebig, it seems, is willing to account for this without assuming a corresponding diminution of animal heat, through the increased formation of water which will take place when alcohol is the combustible material. On the other hand, Dr. Carpenter quotes Bonchardat, who has found that "when alcohol is introduced into the system in excess, the blood in the arteries presents the aspect of venous blood;" showing that it has been prevented from undergoing the proper oxygenating process. Now Liebig's explanation

is good against the mere deficiency in the evolution of carbonic acid, used as an argument against the moderate use of alcohol, while the experiments of Bouchardat relate to alcohol as introduced in excess (and, I may add, what is equivalent to excess, on an empty stomach, when venous imbibition will be rapid); under which circumstances it may reasonably be expected to influence the colour of the blood: accordingly they do not apply to the question of moderate use. Here the allegation of mischievousness against alcohol is founded on conditions which are not realised: nor, in the remainder of this part of the work, can I find one argument *made good* against a moderate use of fermented liquors that is not based on some hypothesis equivalent to the supposition that, because an eminent statesman once died of apoplexy the day after eating twelve mutton chops for dinner, the introduction of two mutton chops daily into the system would end in apoplexy. But I may here be answered, mutton chops are not a poison, and alcohol is—at least, according to the author of the Prize Essay. I reply that the meaning of the word “poison” must be unduly stretched if compelled to bear out this view in toxicology.

Thus, again, the quotation from Dr. Hawkesworth, who, in his Voyage to New Zealand, makes peculiar mention of the facility with which wounds heal in the New Zealanders, who at that period drank nothing but water, is rendered inoperative on Dr. Carpenter's physiological argument against a moderate use of alcoholic liquors by his own comments upon it; for he opposes it, not to such moderation, but to “the unquestionable fact that habitual excess in the use of fermented liquors produces a condition altogether opposed to the healthful performance of these processes.” This point I willingly concede to him; but I must urge that his admissions in regard to the occasional benefits of alcoholic liquors under cold and strong exertion, when they promptly supply the means of reproducing heat without disintegration of tissues, might, by parity of reasoning, lead him to much further admissions in favour of a moderate use of alcohol under the normal circumstances of a large part of the community. I have been induced to think that Dr. Liebig's expressions

on the latter point have led to a somewhat incorrect appreciation of the waste of tissues by oxydation under muscular action. It is asserted by Dr. Liebig that “a rapid change of matter determines a greater amount of mechanical force, and conversely, that a greater amount of mechanical force expended in motion determines a more rapid change of matter. That the latter of these propositions is true may be readily admitted; but that a rapid change of matter determines a greater amount of mechanical force is absolutely irreconcilable with experience, as various forms of atrophic degeneration testify. It appears to me that the illogical conversion of propositions here made by Liebig is calculated to prejudice us, both in favour of a waste of tissues, and against the means by which it may be sometimes arrested or mitigated with advantage, and in that respect against the use of alcoholic liquors, though suggested by Liebig himself as useful, under certain conditions, for this purpose.

The question of stimulation comes naturally before Dr. Carpenter in reference not only to excess, but to the moderate habitual use of alcoholic liquors; and to the latter, as well as to the former, is applied the well-known objection of collapse and debilitation, as presumably involved. On this point I have a few words to offer. The word “stimulant” is rather vague: I will define it for my present purpose, whatever is introduced into the system as being promotive of energy irrespectively of, or in the absence of, any nutritious element contained in it. In many instances nutrition alone is sufficient for the production of energy—that is to say, no element is wanted for this purpose that is not contained in the nourishment required to supply the waste of tissues. With some the energy generated out of this source is such, that the amount of food has in some measure to be diminished for the prevention of excitement—i. e., excessive energy. In others—and this latter category is a very extensive one among the educated classes, particularly with those who live in cities—the stock of energy fit for the purposes of life, and suited to the health of the system, is best maintained by being made up in part through certain innutritious or apparently nutritious substances, which are stimulants according

to the above definition. It is to be observed that these persons are always and normally in that state, which Dr. Carpenter appears to consider exceptional, and to which he allows moderate alcoholic stimulants, on the ground of "deficiency of other adequate sustenance." But he does not seem aware how large a category this exception applies to. The principal of these stimulants in European use are alcoholic liquors, tea, coffee, and opium. Of these each and all have their own modes of subsequent collapse; each and all require prudence and temperance in their use; each and all are appropriate only to certain constitutions. I believe, indeed, that of those who require some stimulant, a very large class would be much prejudiced if compelled to depend upon tea or coffee; nor would the hypothetical advantage of theine and caffeine containing the nitrogenous element of life be a compensation to the persons who may be suffering from the malaise in some cases produced by each, and the heating properties of the latter. Dr. Percival, by the way, has pointed out to us, and illustrated his opinion, that wine is the appropriate remedy for the *mischievous* effects of tea.

Now all the three classes of men in reference to whom I have considered the doctrine of stimulation, are obnoxious to the collapse and other effects connected with mismanaged excitement. To all of them the same precautions, in kind, are required, which Dr. Carpenter limits to the alcoholic sources of energy. But I cannot go along with him in considering "that the moderate use of them will manifest itself sooner or later in diminution of the digestive power; that we may with the highest probability, if not with absolute certainty, attribute many of those chronic disorders which affect the digestive apparatus, the excretory organs, and the nervous system in advancing life," to the "excessive action to which they have been subjected under the stimulating influence of alcoholic beverages" *moderately used*; and it is to their moderate use that he addresses these strictures.

In regard to this point, indeed, the arguments drawn by him from the abuse against the use of these gifts of Providence comes into play in a very insidious manner. Doubtless the alco-

holic excitants *do* some way, even in their moderate use, tend to the production of much mischief to the organs of digestion; in a way, indeed, which has been well illustrated by Dr. Carpenter, with the omission, however, of this point in their favour, that they tend to evil through an instrumentality closely connected with great good. By assisting the primary assimilation, these stimulants can enable the system to take in more nourishment than it requires, or than is consistent with the secondary assimilation. In this case it is not the stimulant, but the food taken in and partially digested through its assistance, which damages. Meanwhile the same stimulant, taken in the same quantity, might enable the digestive apparatus to manage the *fit and normal* quantity of nitrogenised food on easier and more wholesome terms, than if the process of air and exercise were exclusively resorted to for the supply of energy to the nervous functions. I may here observe that Dr. Carpenter's statement in regard to the absence of alcoholic liquors in the training of boxers is questionable. They were not excluded by Mr. Jackson; and it is noticed in the recent translation of the work of M. Franz Simon, that two half-pints of ale are the daily allowance of persons thus situated. I notice this, because, in the palmy days of pugilism, much thought and sagacity were expended in producing in them a very perfect state of health, with a view to an exertion which required both strength and endurance.

But the admission of Dr. Carpenter, in his article from the Review, that if temperance in alcoholic liquors could be established abstinence would be unnecessary, authorises me to believe that he would himself abandon the physiological and pathological assault upon the moderate use of these liquors, but for some doubts which he may be supposed to entertain whether his ethical argument would of itself be conclusive,—whether the enjoining abstinence in all, merely to prevent excess in the many, is quite consonant with sound morality, or is likely to prevent the evil which he deprecates. I now turn to this moral plea in favour of teetotalism; and first to its religious element.

"St. Paul," says the Archdeacon of Bombay, as quoted by Dr. Carpenter,

"accounted one single soul so precious, that he would on no account allow himself in any indulgence that tended to endanger a brother's soul. 'If meat make my brother to offend, I will eat no meat while the world standeth, lest I make my brother to offend. It is good neither to eat meat, nor to drink wine, nor anything whereby thy brother stumbleth, or is offended or made weak:' and we must bear in mind that flesh and blood are here mentioned by St. Paul as good creatures of God; they are not intended to designate things evil in themselves." This saying of St. Paul is the charter of teetotalism: "that is to say, under the guidance of the above application of St. Paul's doctrine, and on the ground taken up by Dr. Carpenter, that "the whole amount of crime, and misery, and wretchedness, connected with the abuse of alcoholic liquors, greatly exceeds the whole amount of benefit arising from the right use of them," the many—for they are many—who find, or consider themselves to find, benefit from the use of fermented liquors, are bound to surrender the virtue temperance to the half-virtue abstinence. Might it not occur to the Arch-deacon of Bombay, if he intends this application of his doctrine, that he erects a something whereby "a brother may stumble, or be offended, or made weak," when he *thus* attaches delinquency to acts performed by thousands of his brethren, which have become, by habit, necessary to the comfort of many of them, in favour of which many of them entertain a strong opinion as conducive to their health, the acts themselves being innocent in their own nature? And such is the moderate indulgence in fermented liquors. I am not obliged by my argument to point out what is the correct application of St. Paul's doctrine: but this, I am sure, is *not*. I will only observe that there is no method of employing the doctrine of Scripture more questionable than that which hastily forms on its denunciations a scheme of positive and conventional delinquencies. But there are texts in Scripture which, by parity of reasoning, might have prevented this error being committed in the case before us. The tendency to anger is one at least as strong, and as liable to be abused, as the tendency to alcoholic stimulants. Yet, of the former, Scripture says, "Be ye angry, and sin not; let not the sun go down

on your wrath." It enjoins even in this case, not abstinence, but temperance. Every scheme of morality in some sort places virtue in the avoidance of extremes; and it were strange indeed if the extreme to which the use of wine and vinous things lays us most open were of such enormity as to become exceptional in reference to this rule, and should interdict the practice in kind, as well as in degree, seeing that the first recorded miracle of our Saviour was performed at a feast, and in increasing the quantity of wine served out to the guests.

The victory over intemperance—and that is the object at which Dr. Carpenter really aims, while he erroneously decries moderation—must be gained by the slow but certain influence of good habits produced by sound education. The attempt to reach that point through the charlatanic expedient of teetotalism will only postpone success by averting attention from the right method of attaining it. The promoters of total abstinence from alcoholic liquors have raised a high structure of argument; but, unhappily, they have not based it upon a just consideration of the moral and social elements of the human mind; and it will sink before the reflux of those tendencies which they have endeavoured to stifle, but which they are only qualified or called upon to check. I suspect that a fallacious appearance of success has been given to the well-intended efforts of Father Matthew by the locality in which, and the circumstances under which, he commenced his labours. Stimulants are convertible; and the physical stimulus is easily superseded, for a time, at least, by moral intoxication, when the latter is congenial in kind. The Irish could easily be led to abandon whiskey by their church, when skilful and unscrupulous agitators were feeding them with a stimulant compounded of sedition and treason. Mahomet succeeded in forbidding the juice of the grape to his followers; but he did not thereby prevent the use of opium: and it is for the teetotallers to consider, while they are substituting particular prohibitions for principles, how far it is prudent to risk a substitution of the same kind with us.

It may occur to any one in reading the above remarks, that they are entirely confined to a detection of supposed errors in an able writer. In answer to

this, I reply, that I am not professing to review the prize-essay of Dr. Carpenter. His work is a strong, but certainly an *ex parte*, attack upon a world-wide practice of society. It is, perhaps, desirable that his views should first be treated critically, in regard to their *ex parte* character, as has been attempted in the foregoing remarks; and when the subject may have been thus sifted, that some competent person should undertake a large and comprehensive view of it in all its bearings.

56, Wimpole Street, Oct. 24, 1869.

CASE OF GENUINE COW-POX VESICLE RISING AT ANOTHER PART THAN THE POINT OF INSERTION.

By ROBERT OKE CLARK,

Late Resident House Surgeon and Apothecary
to the Royal South Hants Infirmary.

On the 26th of August last I was requested to vaccinate John Willesden, *et. 9 months*, a fine healthy-looking child, who, his mother told me, had scarcely had an hour's illness since his birth,—a case promising well that the vaccine should take due effect. I inquired very particularly into the present state of the secretions, &c., and found all in proper order. The breast had been as yet the only source from which his nourishment had been derived.

Three good incisions were made with the lancet in the upper part of the left arm, over the belly of the deltoid muscle, and I inserted into each successively two points well charged with the matter, which had been sent me by the National Vaccine Establishment. Not more than the usual bleeding occurred during the operation, and not the *slightest* abrasion of the cuticle could be seen on any other part of the arm, nor was any scratch made during vaccination.

On the 30th there seemed a slight disposition to the formation of vesicles; but during the next day all redness disappeared, nor did any further signs of the matter having taken effect show themselves at this spot.

On the evening of September 2d the mother noticed what she considered a small red pimple about the middle of the forearm, and, on my visiting the case next morning, she showed it to me. It was then larger, and had, in my opi-

nion, all the characters of a cow-pox vesicle of about the third day after vaccination. I watched the case daily, and became more and more convinced that it was genuine cow-pox. Still, not liking entirely to rely on my own judgment in so unusual a case, on the 6th of September I showed it to my father, and his opinion entirely coincided with mine. It subsequently ran through all the successive stages of a common cow-pox vesicle; and, had I not known in what part of the arm the child had been vaccinated, and that the cuticle of the forearm was previously *quite* entire, I should have unhesitatingly said the matter was inserted at this spot, and that all was going on in a normal way. As, however, I had *never* seen an exactly similar case before (although I have had under my care nearly 1000 cases of vaccination), I confess I was inclined to be rather sceptical on the point, in spite of my convictions to the contrary. I therefore determined to vaccinate the child in the other arm on the 14th day after the primary vaccination, and obtained a fresh supply for that purpose from the National Vaccine Establishment. I inserted into four incisions a quantity of matter from glasses, and subsequently four points well charged with the lymph. No other effect was produced than would have followed a simple scratch—viz., there was a little redness of the part for about a couple of days.

Feeling sure the case was a curious one, I wrote to Dr. Gregory, of the Small-pox Hospital,—one of the greatest authorities of the day, I presume, on these matters,—related the case at length, and asked his opinion. He seemed even more sceptical on the case than I had been, and told me “if the single vesicle were *bona fide* cow-pox, the case was a *very* curious one indeed, undoubtedly the first of the kind that ever happened,” and “that some still stronger testimony would be desirable to prove it such. This testimony would be supplied only by the insertion of *very efficient fluid* lymph into the arm of the same child. If, under such renewed application of an active virus (performed so as to leave no shadow of doubt that the second vaccination had been *decidedly* performed), the child should remain unaffected, we must believe the constitutional vesicle you saw on the forearm was ‘*genuine vaccinia*,’ but, on the contrary, if the second vac-

cination rises into good vesicles, it is clear that the first vesicle was only ecthyma." He advised my giving the child two alterative doses of calomel before again vaccinating him, and offered to charge two lancets for me with "matter of undoubtedly good character." I sent him two, fine and sharp, which he charged from two different children; and the boy was, on Sept. 26th, revaccinated with this lymph about nineteen or twenty hours after it was taken. "This," the Dr. considered, "would put the case beyond doubt;" but he "anticipated that the revaccination would take effect, and that the first vesicle would then be proved to be ecthyma."

However, ~~so~~ such result followed: the vaccination was done efficiently, and the only effect produced was just that which occurred after the first revaccination, and nothing more; not the least inclination ever showing itself for a vesicle to rise. No constitutional disturbance whatever was present.

Dr. Gregory states, "he has seen constitutional vesicles frequently; they are certainly not very common; but then he has always seen at the same time ~~unequivocal~~ primary vesicle." Such has also been the result of my own experience. I have seen them in various parts of the body, but never, previously, as now, *without* a primary vesicle at the point where the lymph was inserted. The same is stated to me to have been the case in the experience of others. May not this case, then, be justly entitled to Dr. Gregory's appellation of very curious and unique?

Farnham, Surrey, Oct. 29, 1880.

THE MEDICAL AND CHIRURGICAL SOCIETY.

At a meeting of this Society on the 29th ult., the following resolutions were agreed to:—

1st. That the trustees of the Society be authorized and empowered to sell £600 stock, to meet the expenses consequent upon the completion of the lease and the repairs of the premises, as authorized by two general meetings of the Society, held on May 1st, 1849, and July 11th, 1880.

2d. That the front drawing-room be appropriated to the general uses of the Society, and that the evening conversations and the meetings of the Council take place there.

3d. That the Council be empowered to let the stables, and such portion of the premises as may not be required for the purposes of the Society.

AN ESSAY ON UNHEALTHY INFLAMMATIONS.

By M. BROOK GALLWEY, Esq.

Assistant-Surgeon Royal Regiment of Artillery,
Woolwich, Kent.

[Continued from p. 712.]

ERYSIPELAS (continued).

Mr. Lawrence's views of the pathology of the disease—His treatment consequent thereon—Their mistaken principles and dangerous tendency.

"Treatment.—As this affection resembles other inflammations in its causes, symptoms, and effects, so it must be treated on the same principles; that is, on the antiphlogistic plan. Venesection, local bleeding, purging, and low diet, are the first measures, to which saline and diaphoretic medicines may be afterwards added. The earlier these means are employed the better: vigorous treatment in the beginning will often *cut the attack short*—(this I can easily imagine—*very short!*)—and prevent the disease from spreading beyond its original seat." (pp. 39-40).

Pursuing the system of education so profitably worked out into practical development by the immortal *Mr. Squeers* (whose custom was first to instruct his youthful disciples in the conjugation of the active verb "to clean," and in the declension of the noun-substantive "windows," and then to afford them the means of carrying out the theory upon his own premises), Mr. Lawrence, after, as I have now shown, elucidating the theory of *slaying "made easy,"* proceeds to illustrate his principles by some practical examples:—

"A patient, 57 years old, was admitted under my care at St Bartholomew's, for an extensive laceration and detachment of the scalp, caused by falling down a flight of cellar steps. From the 3d of June to the 14th he was *bled eight times (!)* from the arm. All symptoms of excitement had ceased on the 15th, when the head was easy, the pulse quiet, and his state favourable in all other respects. On the 18th, erysipelas appeared in the arm and neighbouring part of the fore-arm, the affected parts being tumid, bright red, and very painful. He *died* on the 21st, the erysipelas not having extended beyond the parts first affected." (pp 7-8.)

Now, I think it may legitimately be asked, upon a review of this case, how Mr. Lawrence explains the setting up of erysipelas in the present instance, after the abstraction of (probably) eight pounds of blood from the gross amount in circulation, if the conditions necessary for the establishment of this inflammation are such as constitute a state of *hyperæmia* of the system—an exaltation of the sthenic powers of the individual?

Or, to put the question in a plainer shape, is it easy to conceive a case more felicitously illustrative of the position that erysipelas is a disease of *feeble power*, and that "the expressions of passive and asthenic inflammation" are neither "unmeaning, nor calculated to convey erroneous notions?"

The next case that I shall notice is one of the most *striking* description, and in which the issue was happily less unfavourable than in that I have just recorded. The reader will not quarrel with me if I give it in *extenso*. It is interesting as confirmative of the tenets of some modern Sangradores, who cleave to the canon of their illustrious progenitor, that it is an *error to suppose that blood is necessary for the support of our species!*

Mary Carter, aged 19, was admitted into St. Bartholomew's Hospital on the 26th of April, 1826. The patient, who is in service, acknowledges that she has been in the *regular habit** of drinking freely of gin and porter. She has suffered for seven years with disease of the nose (lupus). The ulceration, which has caused considerable loss of substance in the *alæ nasi*, and an aperture in the septum large enough to admit the end of a finger, has been cicatrized for some time; the surrounding skin exhibits patches of scurfy redness. A few days ago she had shivering fits, and afterwards headache, with heat of skin, and erysipelatous redness and swelling of the face, which had increased so much by yesterday, that the eyelids were quite closed."

These symptoms increased, and were accompanied with "severe headache and a *small and rapid* pulse:" but, as there was nothing peculiar in the symptoms, I shall content myself with the recital of Mr. Lawrence's treatment of the case:—

* The "regular habits" of this young lady remind me of the character in the Spectator, who boasted of his "regular habits of irregularity," in never missing the going to bed with a "stitch in his wig" for forty years of his life.

"April 26th (day of admission).—Fourteen ounces of blood taken quickly from the arm.*

27th.—"Venesection to sixteen ounces."†

May 5th.—"Venesection to twelve ounces."‡

18th.—"Venesection to fourteen ounces."

12th.—"A dozen leeches were applied to the temples."

30th.—"Venesection to twelve ounces."

June 2d.—"Cupped on the back of the neck to sixteen ounces."

12th.—"Bleeding to deliquium."

13th.—"About twelve ounces of blood were taken;" also, on same day, "Eighteen leeches to the temples."§

14th.—"Repeat the leeches" (eighteen, I presume)||

15th.—"Twelve more leeches."

18th.—"Eighteen leeches to the head."

27th.—"Ten leeches were applied."

July 3d.—"Cupping on the neck to fourteen ounces."

4th.—"Twenty-eight leeches were applied to the temples with great relief."

23d.—"Cupping to fourteen ounces, and a dozen leeches in the evening."

August 3d.—"Twenty-four leeches to the temples."

"Discharged on the 7th of August, feeling and looking quite well."

This poor girl had again the *advent* (!) of Mr. Lawrence's professional services in the October following. "She was readmitted on the 19th" of that month, "having continued in excellent health till a week ago, when her left

* "A dose of calomel and jalap was ordered" on the same day. Pulse at this date "small and rapid."

† "A dose of calomel and jalap," &c.

‡ "Pulse small, and 140."—"An aperient draught immediately; saline medicine, with antimony, every six hours."

§ Report on 13th.—"She was very faint and ill for several hours after" (the venesection). "The headache continues. The pulse is still excited; skin hot, and tongue foul. She is thirsty, and complains of shooting pains across brow and forehead. She passed the night without sleep, and is now crying, and appears much distressed." For which state of things (pre-eminently symptomatic of loss of blood) "eighteen leeches to the temples, cold cloths to the head" were prescribed. I ought to state that calomel, antimony, digitalis, and jalap, had been intermittently employed for several days before.

|| Mr. Lawrence states in this day's report, "The catamenia have been suppressed since she came into the hospital, adding (artlessly enough) 'previous to admission she always menstruated regularly!' So good a physiologist as Mr. L., should not have forgotten that the menses require blood for their production, and that as *nihil fit!*

eye inflamed, the face swelled again as it had done before, and she became feverish." In addition to conjunctivitis and scleritis (with "considerable pain and copious lacrymal discharge on exposure to light"), "the nose is bright red; the lower eyelid and cheek are red and swollen. She has a frequent pulse, severe headache, foul tongue, and costiveness."

Treatment.—Loquitur Mr. Lawrence again.

October 19th.—"Twelve leeches to the left lower eyelid."

28th.—"The leeches were repeated." (Twelve, I presume.)

29th.—"The leeches were repeated." (Twelve, I presume.)

30th.—"Venesection to sixteen ounces."

November 3rd.—"Venesection to eighteen ounces."

9th.—"Twelve leeches to the temples."

12th.—"Venesection to sixteen ounces."

15th.—"Cupping on the back of the neck to twelve ounces."

19th.—"Twelve leeches to temples."

21st.—"Twelve leeches."

December 4th.—"Twelve leeches to the temples."

27th.—"Cupped to twelve ounces."

31st.—"The evacuation was repeated."*

Jan. 2d.—"She left the hospital by her own desire, being free from pain, with natural expression of countenance; regular bowels, and rather feeble pulse (f)"

Now, if the gentle and contemplative reader doubt that this is a "true copy," or suppose that I have "set down aught in" (scientific) "malice," I entreat him to turn to pages 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, and 100, of the volume from which I have drawn these materials.

It may not, in sequel to this narration, be an unprofitable employment if we make a mathematical estimate, as far as such is attainable, of the exact quantity of blood which Mary Carter afforded Mr. Lawrence for the prosecution of his physiological experiments. The following table will afford a bird's eye view of the matter. The reader will remember

that demonstration was to be a prominent feature of the present undertaking.

* It is enough here to mention, in a general way, that on this second occasion the lancet was supported by that faithful triumvirate, calomel, antimony, and a league, the evil doings of which, Mr. Editor, that, as one of the staples of our Commonwealth, you yourself to put down.

might that Mr. Lawrence would not for setting down the "bleeding his date, at 14).

the amount of blood drawn by fixed the work done at half I believe the ordinary cal-

It has thus been shown that, during a period of something less than six months, the unfortunate subject of this history was robbed of *twenty-one pounds and a half of blood* by direct abstraction, and God knows of how much more, indirectly, by drastic purgatives and violent sudorifics. One's hair stands on end with very horror at the narration! *Twenty-one pounds and a half of blood from a young lady of 19, of irregular habits, and of an unhealthy diathesis!* The pious Æneas, when the gods appeared to him in his dream and entreated him to fly from Crete, was not more affrighted than was I on perusing this account; and his soliloquy on that occasion scarcely exaggerates the expression of my feelings on this:—

*"Talibus attonitus visis ac voce,
Tum gelidus toto manabat corpore sudor!"*

Now, it has been estimated by physiologists (at a rough calculation), that the quantum of blood in a healthy individual bears the relation of 1 to 5 of his entire weight; so that if we suppose Mary Carter to have weighed 100lbs. (an estimate with which I presume the reader will not find fault), we observe that she surrendered the *last drop* in her possession (and *something more*) to her insatiable physician!

Mr. Lawrence, therefore, must be allowed the merit of having proved to a demonstration the truthfulness of Sangrado's doctrine,—"*C'est une erreur de penser que le sang soit necessaire à la vie.*" And these philosophers together may claim the credit of pointing out the fallacy of the Divine fiat, that "the life of all flesh is the blood thereof."†

Happy, indeed, should I be were these the *only* instances in which I felt myself called upon, by the interests of this important subject, to animadvert upon the consequences of what Mr. Lawrence must forgive me for calling his false

doctrines in connexion with inflammation.

The last five cases of erysipelas in Mr. Lawrence's paper are remarkable enough. It is essential to my present purpose to notice them.

"CASE XXXII.—Charles Neale, a knife-grinder, æt. 47, after having been observed to be altered and strange in his manner, first made a cut in his fore arm, and then a large deep wound, from side to side, in the upper part of the neck. The report does not state, although it is not improbable, that the man lost much blood on the occasion. On the day subsequent to his admission he was bled to 3xvi. for pain in the head and feverishness. Three days later he was bled twice, 'twelve ounces being taken in the morning, and sixteen in the evening;' and, on the following, had 24 leeches applied to the fore-arm, which had begun 'to look red, and to be painful.' The same number were repeated, two days later, 'for an extension of inflammation in the fore-arm, with fever.'"

"In three or four days the local mischief had increased, and assumed the form of phlegmonous erysipelas, affecting the whole fore-arm and ascending the arm." Suffice it to say, that to meet this emergency, Mr. Lawrence "made two incisions through the skin and cellular membrane of the fore-arm, extending nearly the length of the limb. Blood flowed from these, at first rather freely;" fainting ensued, and the patient died before the state of syncope could be overcome. Mr. Lawrence adds, that little more than twenty ounces of blood were lost on this last occasion.

"Mr. Lawrence observed to the pupils, that the fatal event of this case was one of those unusual occurrences, which neither the circumstances of the patient before, nor the examination after death, could elucidate. It might be compared to death from syncope in venesection, which had occasionally happened."*

In the daily detail of the preceding case, we are informed that the poor creature, the subject of it, had, after his self-inflicted violence, evinced "great uneasiness of mind, and a persuasion that he should not recover"—a state of

* Mr. Lawrence disbelieving in the existence of æsthenic or low forms of inflammation, the reader will scarcely be surprised to find this eminent surgeon entirely disregarding, in his treatment, the generally acknowledged axiom, that intemperance so modifies the healthy tone of the nervous system as to render the subjects of such peculiarity intolerant of loss of blood. This may not be an unfitting place to remark upon Mr. Lawrence's infidelity in relation to another canon in medicine. I allude to the well-established principle, that depletion is very differently borne in London and other large towns from that which obtains in country districts.

† Leviticus, chap. xvii. v. 14.

* Med.-Chir. Trans. vol. xiv. p. 176. This case is transcribed from the Lancet, in which it had originally been published.

things denoting how greatly the nervous system was implicated in the mischief going on, and eloquently pleading for the aid of stimulants and opium. The abstraction of large quantities of blood under such a state of innervation is at all times a most hazardous practice; and, sudden death ensuing thereon, a result not unreasonably to be looked for. It was long ago remarked by an illustrious writer—"Cor, vitæ atque roboris principium est; in eo anima, et natura ejus locatur. Quare *syncope*, cum cordis vitæque morbus sit, humanæ constitutioni planè adversaria est, et vinculorum quædam dissolutio est, quibus facultas continetur vitalis.*"

"CASE XXXIII.—John Cogan, a very tall man of *unhealthy* appearance, received a severe blow on the ankle, to which he paid no attention, until the foot and leg inflamed and became so painful that he was obliged to discontinue his ordinary labour." Was admitted under Mr. Lawrence; had *thirty* leeches applied to affected part; took purgatives and antimony, &c. Next day, *thirty* leeches more; and on the third, venesection to 14 ounces. Ammonia was subsequently administered. Still later, incisions were practised in the erysipelatous part, from which, through "the negligence of the attendants," much blood was lost, and the patient in the bargain.

"CASE XXXIV."† will demand from me a little more detail: a most instructive lesson may be learnt from it.

"Mr. James B——, æt. 36, of bilious habit, had been in very good health latterly, though subject to occasional inflammatory swelling of the glands

near the internal condyle of the right os brachii. On the 22d of February, 1827, he examined, at eight o'clock in the morning, the body of a patient who had died of phthisis pulmonalis."

In the evening he felt unwell, but, next morning early, he was sensible of an inflamed, swollen, and painful state of the glands, before alluded to. Rigors, headache, and so forth, came next; "the pulse was 90, soft, and in no respect *unpleasant (!)*" (Query, is Mr. Bullen from the *green* Isle, where one hears, occasionally, such expressions as an *elegant tune*, a *handsome day*, and, possibly, a "*pleasant pulse?*") "The breathing" was, we are informed, "heavy, with a sensation of oppression at the præcordia, the breath expired from the lungs being very hot, and as though boiling." "Countenance flushed; pupils rather *dilated*."

"Twelve ounces of blood to be abstracted from the neck by cupping; twelve leeches to the arm."

"11 P.M.—Twenty-four leeches to the temples;" hyoscyamus; cold lotions to head.

24th.—Arm being "more swollen and painful," with increase of pain and headache, patient had six leeches to inflamed part, and was bled to ten ounces.

25th.—"Arm not worse;" "considerable heat and pain about the head;" twenty leeches to temples; and, at night, venesection to twenty ounces.

27th.—A dozen leeches to the arm yesterday: twelve to temples, with cupping at back of head, to-day. *Erysipelas* had extended to shoulder.

28th.—The inflammation having extended to the body, Mr. Lawrence was now called in, who made two incisions in the arm, "from which from two to three pounds of blood were lost, when partial syncope came on, *during which several stools were passed*. He complained of loss of sight, together with an indescribable sensation of alarm, as he expressed it, in the whole line of the spinal cord."

March 1st.—In addition to partial loss of sight, and the other serious symptoms recorded in the last report, hiccough and stertorous breathing had now been superadded. "Dr. Back saw him" at 3 P.M., "and declared his belief that he had not lost a drop too much blood (!), and that his present symptoms did not arise from loss of blood." (!)

Mr. B. died on the day after.

* Aretæus.—"De Aretæi in rebus Anatomicis Scientia," p. 17.—Some years ago a case fell incidentally under my notice, which has left an indelible impression upon my memory. A fine athletic man, about thirty years of age, who was greatly addicted to the bottle, but who had none of the characteristics of the drunkard in his physiognomy, was overtaken by an attack of delirium tremens, of by no means a formidable character. When I saw him, I believed him to be convalescent (not being in attendance upon him); for he had left his bed, and was up and dressed. I conversed with him for some minutes, when he was not only rational, but appeared to me to be in his ordinary health. I subsequently learnt that, not many minutes after I had left him, he became delirious again, and died suddenly in his chair. I had no reason to believe that he was the subject of organic disease. But his nervous system was gone. Whiskey and the tropics together had literally "*unnerved*" him. The case occurred in the Isle of France.

† This case was communicated to Mr. Lawrence, by Mr. F. Bullin. *Vide Med. Chir. Trans.* vol. xiv. p. 190, et seq.

Mr. Lawrence remarks upon this case as follows. "The local and general means, although active, and followed up without delay, had altogether failed to arrest (query, *increased?*) the inflammation, and the treatment by incisions offered, in my judgment, the only chance of saving the patient. The adipose and cellular texture was found highly inflamed, *loaded with serous effusion*, and assuming here and there the yellowish appearance which precedes sloughing. There was no suppuration." "It is clear from the narration of Mr. Miller," adds Mr. Lawrence, "that the progress of the local mischief was arrested by the incisions, and that they produced, what all the previous measures had failed to effect, a very marked diminution of the inflammation. Whether the fatal event happened in consequence or in spite of them is a question on which opinions will differ, and light would probably have been thrown by examination of the body.

"It does not appear to me," Mr. L. continues, "that Mr. B. died from loss of blood. It has been suggested that he perished from the shock of the operation." This idea Mr. Lawrence thinks unsupported by the evidence, and I quite agree with him in the opinion.

"When we consider how often death has ensued from wounds received in dissection under various plans of treatment, we need not be surprised at a fresh instance of fatal termination. When we reflect, further, that both the local and general symptoms were severe in this case, and that at the time of making the incisions the inflammation not only occupied the whole upper extremity, but had even extended to the body, we may reasonably doubt whether the event of the case was in any way owing to that treatment."

The last case which I shall notice, though rather one of diffuse inflammation of the areolar tissue than of erysipelas, has an interesting relation to my present purpose.

A gentleman, *ætat* 64, a free liver, with a pallid complexion, and who suffered much from gout, sought Mr. Lawrence's assistance on account of stricture of urethra. While under treatment for this affection he indulged freely on two successive days in the pleasures of the table, and on the third exposed himself to a cutting east wind, which brought on fever, and an cedematous swelling of the throat. Twenty ounces

of blood, by cupping, were taken from the back. In spite of this, "the swelling about the neck and jaw increased, with difficulty of breathing." On the following day both these symptoms had increased, and become much more urgent. The heart was beating most violently. "He had not only felt, but heard, its violent palpitation: the pulse was about 144, and still rather full and strong." "I took eighteen ounces of blood from the arm: the landlady of the lodging-house had already applied leeches to the chest: the pulse sunk considerably; but the breathing, although easier, was not essentially relieved: the countenance was pale and anxious, and would alone have indicated great danger." The patient never rallied after this.

Such is a hurried sketch of the principles and practice of this eminent authority in relation to the disease we have in hand, as didactically paraded before the first scientific institution in the world for the approval and instruction of the profession at large.

Now, I hesitate not to assert (and I do so with the utmost deference to his high standing as a surgeon and a physiologist), that Mr. Lawrence has entirely mistaken and misunderstood his subject, and that it is out of his own mouth that I derive the evidence which condemns him. His own cases incontrovertibly prove this position.

"I am quite at a loss to discover in this affection those marks of debility which some have so much insisted on." "Indeed, speaking of the part, I am unable to recognize debility as the cause of any inflammation whatever; and in reference to the seat of disease, I regard the expressions of passive and asthenic inflammation and venous congestion as either unmeaning, or calculated to convey erroneous notions."—Pp. 28, 29.

Now, the very first case which Mr. Lawrence brings forward to illustrate his principles, and which I have extracted verbatim from his essay (p. 7—8), affords, in my opinion, so complete an overthrow of his entire fabric, that I would not desire a stronger argument to support me in an *opposite* view of the nature of erysipelas. A man, fifty-seven years of age, experiences a wound of the scalp, for which he is bled *eight* times from the arm in little more than as many days, *i. e.* between the 3rd and 14th of June. On the 18th, erysipelas appeared in the arm and neighbouring

part of the fore-arm! If inflammation bespeaks a necessarily *sthenic* state of the heart and sanguineous system generally, or of either alone, can any man in his sober senses believe that such a condition was set up in the present instance within four days after this enormous unloading of the bloodvessels? And yet such is the necessary—the unavoidable, conclusion from Mr. Lawrence's reasoning! There is no escape from this position.

Again, in the case of Mary Carter (the second I have related), the erysipelas of the face first made its appearance on the 26th of April; yet, despite the almost daily abstraction of blood from that date, the report on 27th of June states that "her countenance is *again swollen and bright red;*" and on 23rd July, "the face is *very red and swollen.*" She was discharged on the 7th of August, after the loss of *thirteen pounds and a half of blood;* yet, in the October following, so *stubbornly sthenic* was the state of her system, that the original inflammation broke out afresh, and demanded the removal of eight pounds more for its subdual!

Yet, Mr. Lawrence is "quite at a loss to discover" in erysipelas "those marks of debility which some have so much insisted on."

Mr. Lawrence's *sixth case** (not previously noticed) occurred in the person of a girl *æt.* 23. Whilst the fauces and one side of face are erysipelatous, "the pulse is *extremely rapid and feeble;* there were thirty-eight pulsations in a quarter of a minute as she sat in a chair after her throat had been examined. She is so weak that she cannot stand without support. The tongue is tremulous, and obeys the will imperfectly." "In the evening a state of stupor, with *increased determination of blood to the head, was found,* (!) and the insensibility seemed approaching to the state of coma; the pulse still rapid and feeble." The *erysipelas continued to extend the while;* yet, Mr. Lawrence regards the expressions of passive and asthenic inflammation as either unmeaning, or calculated to convey erroneous notions!

I cannot resist affording the reader a taste of Mr. Lawrence's quality in the science of "summing up," as disclosed to us in the sequel of the foregoing case.

"The advocates for the use of bark

and wine in erysipelas would probably have considered this a fit case for that plan of treatment. I felt doubtful, in the first instance, what course ought to be adopted, and gave conditional directions for the management of the patient. In spite, however, of the depressing circumstances to which she had been previously exposed, as well as of the *supposed evidences of debility* (!) which she exhibited on her admission, stimuli were obviously injurious, and she derived great benefit from repeated alvine evacuations."

Mr. Lawrence having himself established the fact that erysipelas will *arise* during a state of extreme prostration of the powers of life, and, of course, of those also of sanguification, as instanced in the preceding case ("the pulse is extremely rapid and feeble:" "she is so weak that she cannot stand without support"), and that the removal of thirteen pounds and a half of blood affords no guarantee against its recurrence, affords numerous examples of another no less important practical fact,—to wit, that the removal of blood and the decline of the disease bear no reciprocal relation to each other. In many of his cases, the more he depleted, the more did the erysipelas persist. This circumstance is strikingly shown in "Case 5th" (that of Mary Carter), as well as in "Case 34" (that of Mr. James B.).

Am I not justified, then, in the assertion that Mr. Lawrence has mistaken or misunderstood his subject, and that he has failed altogether in establishing the relationship between erysipelas and a sthenic state of sanguification? Nay, may I not go a step further, and assume that he has done good service to the real interests of this question, by the very facts which he has brought forward in support of an erroneous and mistaken theory?

But if Mr. Lawrence's views of the nature of erysipelas are incorrect and unsupported by the facts which he himself advances for their elucidation, how pernicious must not be the *practice* which they inculcate! And here I cannot help inviting attention to what to me appears to be a frequent misinterpretation, on the part of Mr. L., of *purely nervous phenomena* for those expressive of inflammation. In no other way can I account for his obstinate persistence in a depletory line of treatment in the face of such *manifest* and

* Loc. cit. p. 100.

dance as his own detail affords of its inutility and impotency in controlling the conditions to which it is addressed. Dr. Marshall Hall in one of his works has addressed a caution to the profession which should be engraven in letters of gold over the portals of every institution for the treatment of the sick, and indelibly, on the understandings of every practitioner,—which is, that *where one abstraction of blood has been unattended*

with good results, we should hesitate about the propriety of repeating it. I believe that no safer guide than this will befriend us in practice, and I earnestly press its importance upon the consideration of my brethren; for, let us not forget the admonition of Hippocrates himself to the physician—"To do good, or, at least, to do no harm." (Epidemic 1.)

[To be continued.]

**FURTHER OBSERVATIONS
ON THE
EXISTENCE OF OXALATE OF LIME
IN THE URINE,**

IN CONNECTION WITH STRUMOUS ENLARGEMENT OF THE LYMPHATIC GLANDS.

BY THOMAS BALMAN, M.R.C.S.,
Surgeon to St. Anne's Dispensary, Liverpool.

Formation of Dumb-bell Crystals of this Salt from the Decomposition of Lithic Acid.

In pursuing some inquiries relative to the histology of scrofula, and more especially that form of the disease characterized by enlargement of the cervical lymphatic glands, I was led by microscopic examination of the urine to notice the very frequent occurrence of oxalate

of lime as a constituent of that secretion.* Since this period, I have continued these investigations, in order to ascertain the comparative frequency of this salt in other diseases, and thereby, to some extent, test its value as a pathological indication of the strumous habit referred to. With this object I have examined specimens of urine in a great variety of cases; the majority from persons applying indiscriminately to the dispensary; others from the wards of the Liverpool Infirmary patients of Drs. Dickenson and Turnbull, who were so obliging as to assist me in procuring specimens for examination in every possible way.

The number of cases of which I have specially recorded notes amounts to 140; of these 28 were well-marked instances of strumous glandular affections of the neck. They are classed in the following order:—

	No. of Specimens examined.	Ditto containing Oxalate of Lime.	Oxalate of Lime un-mixed with any other Deposit.	Oxalate of Lime and Lithates.	Oxalate of Lime and Phosphates.	Per Centage of Oxalate of Lime in Cases examined.
Bronchitis	5	2		2		Per Ct. 40
Phthisis	21	10	5	4	1	47
Rheumatism	8	1		1		12
Organic lesions of the nervous system	7	2	1	1		28
Stomach affections	18	6	3	3		33
Bright's disease	3					
Affections of the skin	12	8	4	4		66
Secondary syphilis	10	3		3		30
Rickets & scrofulous disease of joints	11	4		3	1	36
Cases not referable to any of the above	22	9	3	5	1	40
	117	45	16	26	3	38
Scrofulous gland cases	23	17	10	6	1	74
	140	62	26	32	4	

* See MEDICAL GAZETTE for August.

The Relative Proportion of Instances in which Oxalate of Lime was found Mixed and Unmixed with Lithates will stand thus:—

The 117 Cases taken collectively.		Scrofulous Gland Cases.	
Oxalate of lime	45 give 16, equal to 35	Oxalate of lime	17 give 10, equal to 59
unmixed	per cent.	unmixed	per cent.
Oxalate of lime	45 give 46, equal to 57	Oxalate of lime	17 give 6, equal to 35
with lithates	per cent.	with lithates	per cent.

By the above it will be seen that, taking the 117 cases together, oxalate of lime is found in the urine in 45, or about 38 per cent. In the scrofulous gland cases the proportion is 17 in 23, or 74 per cent. There is one group of cases in which the oxalates appear to be very generally met with: I allude to skin affections, amounting to 66 per cent.: of these 4 were cases of impetigo, in all of which this salt was detected in considerable quantity; 5 were cases of psoriasis, in which it also appears not uncommon. In secondary syphilis I only found it in the more inveterate forms of the disease characterized by deep ulceration of the palate and soft parts of the throat.

As regards stomach affections, my observations do not show so large a proportion; and, indeed, I failed to detect the oxalates at all in a great majority of those severe dyspeptic cases with which it has been by other writers so commonly associated.

In disease of the bones and joints commonly regarded as scrofulous, the oxalates are very frequently replaced by earthy phosphates. In four cases of mollities ossium this was very remarkably exemplified; abundance of beautiful prismatic crystals of the ammoniacomagnesian phosphates hardly requiring the aid of a microscope, being found in each of the specimens.

This leads me to notice one or two interesting facts regarding the disappearance of oxalate of lime in phosphatic urine, which I do not recollect noticing elsewhere. In a former paper I mentioned that a large proportion of specimens in which oxalate of lime was absent from the urine were precisely those in which the alkaline or earthy phosphates were in excess. In the present series, taking the whole 140 specimens, it will be seen by referring to the foregoing table that oxalate of lime was associated, in four instances, with an excess of phosphates; once

only with a distinct sediment of prismatic crystals; and three times with a probable excess, as indicated by heat and its resolution by nitric acid. On examining the former specimen the following day very carefully, I failed to detect a single crystal of the oxalate of lime. Having some other specimens of oxalic urine at hand that had been standing for some time, I remarked that in those which had become putrescent, and therefore deposited phosphates, that the oxalates had likewise disappeared. To test this phenomenon more fully, I procured two specimens of urine from different persons, passed the previous night,—one containing octohedral crystals of oxalate of lime in considerable quantity, unmixed with any other sediment, and strongly acid to the blue litmus paper; the other, alkaline, and depositing prismatic crystals of the triple phosphates. On mixing the sediments of these two specimens in about equal proportions, I found that after standing forty-eight hours the oxalates disappeared, and the phosphatic crystals assumed a beautiful feathery appearance in place of the prismatic form. I have repeated this several times, and almost uniformly with the same results.

I have not observed the same thing to happen in urine holding phosphates in solution, nor so constantly when depositing the peculiar basic star-shaped crystals. In a few instances I have observed the oxalates to disappear in urine, neither alkaline or phosphatic, in a much shorter time—six to eight hours, but the exact circumstances in which this happens I have not been able to determine.

This, however, I have reason to believe is of no frequent occurrence, as commonly this salt remains for months in the same urine when unmixed with any other deposit, the liquid still retaining the urinous odour without the least sign of putrescency. This may not be alone peculiar to oxalic urine; but I

do not recollect to have noticed the same thing in specimens not containing this salt.

We have seen that oxalate of lime is rarely found in phosphatic urine, and my observations further go to show that the one diathesis does not succeed the other. The phosphatic may follow the oxalic diathesis. The reverse does not seem to happen in a general way—that is, oxalate of lime, as a constituent, very seldom alternates directly in urine frequently abounding with earthy phosphates. And here I wish to be understood as speaking of something like a permanent condition, as I am quite satisfied that many temporary variations, depending on a variety of circumstances, may occur at different periods of the same day; and so far my experience accords with the very elaborate researches of Dr Bence Jones.* Thus in scrofulous tumors of the neck I have found the oxalate of lime to persist in the urine for months together, until the health has become so deteriorated, and the powers of the system so reduced, that the earthy phosphates become of no unfrequent occurrence in this secretion: the oxalate of lime is then seldom met with, and rarely directly follows it. For example, one day a specimen may show a well-marked instance of the earthy phosphate; the next or following day, by procuring the urine passed separately by the same person at night and first thing in the morning, the former, for instance, may be quite free from the oxalate, or any other sediment, whilst the latter will show oxalate of lime and lithates associated together. Oxalate of lime, therefore, seems to succeed the phosphates only by the intervention of lithates. Dr. Prout arrived at much the same conclusions when he wrote the following:—

“The oxalate of lime diathesis is preceded and followed by the lithic acid diathesis—a circumstance which seems peculiar to these two forms of deposit; and, when taken in conjunction with the other circumstances already related, appears to show that they are of the same general nature—or, in other words, that the oxalic acid merely takes the place, as it were, of the lithic acid, and, by combining with the lime naturally existing in the urine, forms the concretion in question.”†

That the two deposits are frequently met with together in a great variety of diseases, the foregoing table, framed with some degree of care, abundantly testifies. It also illustrates one other point to which I wish to draw attention—viz., the comparative frequency of oxalate of lime as a constituent of the urine in the respective diseases mentioned, as well as the particular deposit with which it is commonly associated. In comparing together the 117 general cases collectively with the 23 strumous gland cases, a striking difference will be observable in each of these respects: in the former, for instance, the oxalate of lime is unmixed with any other deposit in 35 per cent. of the specimens; mixed with lithates in 57 per cent; whilst in the latter we have directly the reverse—unmixed, 59 per cent.; mixed with lithates, 35 per cent. In the one case, so far as my observations have gone, the oxalate of lime may appear and disappear with the lithates, or be of no long continuance in the urine; whilst in the other (scrofulous gland cases) it is, so to say, permanent—that is, continuing for weeks, or more commonly months, uninfluenced by diet or medicines of any kind. This appears to me an important distinction, the truth of which I have confirmed by careful and repeated examination of the urine, from time to time, of persons labouring under this unusually rebellious disease. They have been desired to abstain from sugar, and every other dietetic substance likely to be converted into oxalic acid during the primary assimilative process of digestion, without much effect: nitro-muriatic acid, given for a considerable time, had only the effect of throwing down a sediment of lithic acid, without producing any decided change in the quantity or persistence of this salt, at whatever period of the day it was examined. As a rule, I believe I may state—for I invariably procured two specimens, one passed at night, the other in the morning—the oxalates were always more abundant in the former, *urina clyli*, than in the latter, *urina sanguinis*. Most of the cases of this disease occurring among the lower orders of people in towns, are generally so tedious and protracted that a sufficient number of cases have not yet fallen under my notice to enable me to say positively that this salt disappears from the urine *pari passu* with

* Lectures on Animal Chemistry—Lawes.

† Prout on Stomach and Urinary Diseases, 2d ed.

the subsidence or removal of the enlargement; but in those cases that I have seen where the disease had got well, and the general health improved, the urine no longer exhibited any traces of the oxalates.

I have not seen the peculiar unaciform or dumb-bell form of these crystals, first noticed by Dr. Golding Bird, more than three or four times: they were in every instance preceded by and associated with octohedral crystals, and were rarely found to be of any long continuance, though the latter continued unchanged. That they are in reality some modification of the octohedral form, and may, like the latter, be formed readily by the decomposition of uric acid, the following experiment, I think, will be considered as conclusive. Take any specimen of urine of moderate specific gravity, free from all traces of oxalate, and add to it a drop or two of nitric acid: in the course of twenty-four hours lithic acid will be deposited at the bottom or sides of the vessel: decant the supernatant liquid, leaving about half an ounce with the crystals; add lime-water until the excess of acid is neutralised, and the fluid becomes turbid; then place it aside for a day or two: if a drop of sediment be then examined under a microscope, you will find perfectly-formed dumb-bell crystals of oxalate of lime, as well as the octohedral forms. In the first experiment there was nothing but dumb-bells beautifully striated for some days, since which I have almost invariably found them mixed with octohedral crystals. I was first induced to try this experiment from once observing a few very minute octohedral crystals of this salt mixed with uric acid in a specimen of urine to which a small quantity of nitric or muriatic acid had been added, and the liquid carelessly set aside for a considerable time. I afterwards repeated this in every possible way without the same success, when Dr. Brett suggested the addition of ammonia, which, however, did not succeed until the addition of lime-water in the way mentioned. I am not aware that any one has succeeded in forming these characteristic dumb-bell crystals in a similar way before. The fact is interesting in two ways: first, as showing that they are probably some modification of the common octohedral form; secondly, that oxalic acid is, as pointed out

by two distinguished chemists, Liebig and Wöhler, a derivative of uric acid; and hence the reason why these two substances are so frequently met with together.* There is one peculiarity in oxalic urine which I do not remember to have otherwise noticed. In two or three instances, specimens of urine, when brought to me, containing oxalate of lime, appeared to remain clear for a considerable time, though the day was not particularly warm, and gradually deposited a rather copious sediment. On examining this in the evening, after an interval of six or seven hours, under the microscope, the deposit was found to consist of nothing but lithate of ammonia and oxalate of lime. On re-examining the same specimen the following morning, the former had completely disappeared, and was replaced by the regular square-shaped crystals of lithic acid, the oxalate of lime remaining in pretty much the same quantity. Whether this arises from the presence of oxalic acid, or the development of a new acid in the urine, I am unable to determine.

Many microscopic observers who have paid much attention to urinary deposits will have noticed the not unfrequent appearance of an occasional globule of starch floating about under the field of vision. On one occasion I found a very copious sediment, consisting of hardly anything else but distinct starch vesicles. The specimen was obtained from a female about 20 years of age, a patient of Dr. Dickenson's in the Liverpool Infirmary. She was apparently affected with some unusual form of paraplegia, and in an extremely debilitated state. The case, I believe, was considered as functional disorder only. The first specimen had the appearance of purulent urine, and the sediment occupied nearly a sixth of the entire liquid. Having some doubts

* I have many times formed octohedral crystals of oxalate of lime by separating and repeatedly washing lithic acid with distilled water, so as to remove any of the other ingredients of the urine, and adding lime-water in sufficient quantity to dispel the greater portion of these crystals after standing two or three days.

In experimenting in this way I have sometimes noticed forms very like dumb-bells, but differing from them by disappearing almost instantly by the addition of acetic acid; and are therefore probably nothing but carbonate of lime.

I have likewise observed crystals of lithic acid, when submitted to this process, assume much the appearance described by Dr. Frick, of Baltimore, only that the central part of the crystal resembled the dumb-bell, whilst it still retained the general outline or framework of the original.

in my mind as to the source of this unusual product, I procured two more specimens, taking care to avoid every source of fallacy by providing perfectly clean bottles, and at the same time cautioning the nurse, who had her under her own more immediate charge. The specimens thus obtained had, however, precisely the same appearance. The sediment was not at all so copious as the former, and exhibited under the microscope a few crystals of oxalate of lime. Dr. Brett saw and submitted each of the specimens to the iodine test under the microscope with me.

I examined a third specimen after the lapse of a fortnight or three weeks, when the urine had become transparent, and without any appearance of this substance. It, however, contained a few large organic globules, epithelium scales, and a considerable quantity of oxalate of lime. In the meantime she had certainly very much improved in her general health and appearance.

I have endeavoured to represent these starch vesicles as they appeared under the microscope in the second specimen. They are all probably from wheat, being smaller than those obtained from common potato starch.

Starch vesicles magnified 200 diameters, and oxalate of lime.

POISONING BY NITRIC ACID.

DR. J. M. WARREN has reported the following case:—The patient was a negress, 34 years of age, of abandoned character, and took the acid at six P.M., on the 3d of March, thinking that she was three months pregnant, and wishing, she said, to destroy her child. The quantity taken into her mouth was reported to be three drachms, but most of it was spat out. Alkalies and mucilaginous drinks were used, but the burning in the mouth was intense during the night, with restlessness and delirium. The next morning she was brought from the jail, where the acid was taken, to the

hospital. Yellow stains were then observed upon the clothing, and the whole inside of the mouth and fauces, so far as could be seen, was of a deep yellow colour, the tongue looking as if covered with Indian meal; the respiration being painful, laboured, and stridulous, and speech almost impossible. Extremities cold; countenance of a leaden hue; pulse 120, and very small. For the first four or five days after her admission she suffered from soreness of the mouth and throat, dysphagia, thirst, and salivation, with some vomiting; she also complained of tenderness of the abdomen, but not particularly over the stomach, walking with difficulty and bent much forwards; but this was perhaps owing to her having been thrown down and stamped upon, in an affray, on the day on which she took the acid. After the first day or two she was much of the time up and about the ward: at the end of a week she was reported quite comfortable, and having some appetite; and on the 14th of March, as she was doing well, she was removed back to the jail, there never having been any fever, but rather a state of depression. On the morning of the 16th she was attacked with cramps in the stomach, and excessive pain and tenderness, which were partially relieved by opiates; on the following morning, however, she was found dead in her cell, with a great quantity of blood about her, and which she had apparently vomited.

On dissection, there was observed great rigidity. Upon the middle of the tongue a large, yellowish, smooth patch. Some redness of epiglottis. Œsophagus healthy for the first two inches; but below this it was found exceedingly soft, of a greenish yellow colour internally, purple externally, and full of coagulated blood. The stomach was in a similar, though much worse state: externally, it had the same purple colour, and was universally adherent to the neighbouring parts by recent lymph, except at the left extremity, where there were old and close adhesions to the spleen; internally, it was of a greenish yellow colour, emphysematous, and so perfectly softened and friable, that it could not be separated from the surrounding parts without giving way in every direction; the anterior face being detached from the rest of the organ to a great extent when the abdominal parietes were raised. Cavity filled with recent coagulated blood, and the open orifices of several vessels distinctly seen on inner surface. The intestine contained blood throughout the first two or three feet, but was otherwise sound, as were the other organs, so far as observed. Uterus not gravid.—*American Journal of the Medical Sciences* for July 1850.

MEDICAL GAZETTE.

FRIDAY, NOVEMBER 8, 1850.

In resuming our remarks on the process for extracting sugar by lead, we consider it unnecessary to quote the details of the Report issued by Professors Thomson, Graham, and Hofmann. These will be found in the Parliamentary paper already referred to. We may merely state that these gentlemen made the discovery, that in the mode of refining sugar which is at present generally adopted, traces of lead are to be found both in the bastards and treacle. This impregnation apparently arises from the use of leaden pipes in the ordinary processes of manufacture, and from the general practice of painting with white lead the inner surface of the metallic cones used as moulds for loaf-sugar. No lead whatever was found in four loaves of sugar refined in different operations by the ordinary process. The Report, however, renders it certain that the refined sugar, bastards, and treacle, generally acquire a trace of lead from the *new process* sufficient to be distinguished by chemical tests. We subjoin the conclusions:—

"That the lead found in the refined sugar is minute, the quantity not exceeding that occasionally acquired by the *bastards and treacle in the ordinary process of manufacture*.

"In the bastards of the new process the proportion of lead is not great, but sensibly exceeds the latter standard.

"The lead appears to accumulate in the treacle, but in no case that we have had the opportunity of observing to such an extent as would justify us in pronouncing the treacle to be poisonous.

"The inspection of the process on the large scale satisfied us that the lead may be removed from the sugar to a point beyond danger, provided the operations are constantly watched by a person competent to apply the necessary chemical test of purity to the products,

"In conclusion, although our results do not indicate certain and immediate danger from the use of this process in British refineries, still we must deprecate its extension, on the general ground that poisonous substances should never be used in the preparation of an article of food where they can be avoided; the object effected in this process by means of a poisonous material, the use of which is unquestionably attended with the possibility of grave accidents, being one that is attainable otherwise without danger.

(Signed)

"THOMAS THOMSON.

"THOMAS GRAHAM.

"H. W. HOFMANN."

On the assumption that the specimens had been fairly taken, and the analysis carefully and properly made, this Report was referred to Drs. Pereira, Taylor, and Carpenter, with a statement of the average quantity of treacle consumed by the poorer classes; and their opinion was requested on the probable effects of treacle derived from the lead process on the public health. We find from their Report that the quantity of lead which would be consumed by the use of the patent sugars was calculated as pure metal, probably in order to avoid all objections respecting the actual condition or state of combination of the lead in the sugar. Thus it might be in the mixed form of sulphite or acetate, or as sulphite only, according to the perfection with which the chemical process was carried on. The weight of metal being once determined, the equivalent proportion of any of its salts might be easily arrived at.

It is well known that the Royal Family of France, while residing at Claremont in the year 1848, suffered severely from all the symptoms of lead-poisoning by the use of water containing only a proportion of one grain of metallic lead in the Imperial gallon, or 1-70000th part; and taking this as a basis, the reporters draw the conclusion that the water consumed weekly by each individual, may have contained a quan-

tity of a salt of lead equivalent to 1.75 grains of metal. In from five to seven months this gave rise to most alarming symptoms of lead-poisoning in thirteen adult persons. Had the quantity of lead taken weekly been smaller than this, it is pretty certain, from the well-known cumulative properties of this metal, that it would have been only a question of time. With half of this quantity the effects might have been longer in appearing; but still, if past experience is to be trusted, they would ultimately have shown themselves. Mr. Herapath has stated, in a letter recently published in this journal,* that the use of water containing only 1-500000th part of lead—i. e. *one-seventh* of the proportion found in the Claremont water—gave rise to all the symptoms of lead-poisoning among the inhabitants of a village who used this water: hence it appears to us that the medical reporters have rather under-stated than exaggerated the effects which were likely to arise from the general use of the patent sugars. The returns of the consumption of treacle show that, assuming the chemical analysis to be correct, the quantity of lead consumed at a maximum may be as much as 1.261 grains, and at a minimum, about one-third of this quantity,—i. e., 0.43 grains. The Claremont people were poisoned by an assumed weekly dose of 1.75 grains, although the quantity taken may really have been much smaller. In Mr. Herapath's cases it is not probable that the quantity of lead taken weekly by each individual could have exceeded *half a grain*; and, to have taken this quantity, each person must have swallowed weekly the lead contained in more than *three imperial gallons* of water,—a hard trial to the stomach of one who is not a professed hydropathist. We are the more particular in stating these facts, because the patentees appear to rest their case on

the "innocuity" of small quantities of lead,—a mere delusion to all who, as medical practitioners, are acquainted with the highly insidious nature of lead-poisoning. They admit the facts, but demur to the medical inference,—because, they say, in these water-cases the lead is in the state of a highly poisonous carbonate; while, in the sugar and treacle-cases, it is in the form of the innocuous sulphite! This pretended difference will be a subject of consideration hereafter.

We subjoin the only extract which we think it is necessary to make from the medical report. It embraces the *argument ad hominem*, and goes at once to the probable effects on the public health, of the general consumption of the patent sugars:—

"Perhaps the best test which we can apply to the solution of a question of this kind is, to inquire whether we, by ourselves or our families, would knowingly consume an article of food which would have the effect of transferring weekly into our bodies one grain and a half, or even one grain, of a compound of lead. Our answer is, assuredly not. If we could procure the article of food free from such contamination, we should reject that which contained this proportion of lead-poison; and if we could not procure it in an uncontaminated state, we should prefer abandoning altogether the use of food which might be attended with injurious consequences to health. Even supposing that there were no facts to show that very minute doses of lead-poison taken daily for many weeks may seriously endanger health, the risk is too great to be incurred.

"For the reasons assigned above, it is our opinion that the treacle produced by Dr. Scoffern's process cannot be used as a daily article of food in the quantities specified in the Return, or even in smaller quantities, without exposing those who consume it to the risk of slow poisoning by lead. . . .

"The results obtained by the chemical reporters show that samples of sugar, bastards, and treacle, manufactured with the greatest care by persons well acquainted with Dr. Scoffern's process, do invariably contain a portion of lead,

which is chiefly washed into the treacle. Hence the test and counter-test advised in the process are not capable of showing that the sugar is free from lead, even when these tests are employed by experienced persons. If worked by inexperienced persons, a very large quantity of lead may remain in the syrups, and be diffused through the refined sugar, or carried into the treacle. *Without the constant supervision of a skilful chemist, the public health would be greatly endangered by the general consumption of saccharine substances so prepared*; and, even under this supervision, it would appear, from the analysis of the samples, that while the consumers of refined sugar might possibly escape, the consumers of *treacle* would be liable to suffer, after the lapse of some weeks or months, from the usual effects of lead poison."

Thus, then, the Chemical and Medical Reports confirm those already issued in the British Colonies, and published in our last number. Considering that six gentlemen, whose competency to form a judgment on the premises does not appear to be questioned, and who were employed by Government as a kind of independent Commission to examine and report on the new process without favour or prejudice, and solely with a view to the protection of the patentees on the one hand, and of the public health on the other, have thus publicly recorded their opinions against the new process,—we should have thought that the matter would have been closed, and that nothing further would have been heard concerning sugar refined by lead. If anything were wanting to confirm this view, it would have been the statement which has reached us, on good authority, that the eminent chemist, who happens to be French Minister of Commerce, M. DUMAS, has positively prohibited the introduction or manufacture of the patent sugar in France: and why a man in his position should wish to put a restriction on scientific improvements in manufactures, except

from their probable danger to public health, it is impossible to comprehend. Again, when the subject was brought under discussion at the British Association, in Edinburgh,* the assumption that Sulphite of lead was innocuous,—one of the points on which the supporters of the new process strongly rely,—was condemned as unsound by Dr. Christison, the first authority on Toxicology in Great Britain.

At a recent meeting of the Pharmaceutical Society the process of using salts of lead for the refining of sugar was pronounced to be unsafe by Dr. Ure, Dr. Golding Bird, and other chemists. This accumulation of adverse opinions, however, appears to have had only the effect of making the patentees more active in endeavouring to prove that the process is not only perfectly innocent, but actually safer—i. e., less noxious to health—than the ordinary method of refining sugar! They have put two pleas on the record:—1. That there is no sulphite of lead left in the sugar or treacle when the process is properly conducted; and 2. That, if any sulphite of lead by accident pass into the sugar from defective filtration or otherwise, it is as harmless as chalk, and the sugar may be consumed with impunity.

They have retained as scientific counsel in support of these doctrines, and against the six Government reporters, M. Dumas, and Dr. Christison, two gentlemen—namely, Dr. Gregory, of Edinburgh, and Mr. R. Warrington, of Apothecaries' Hall. Dr. Gregory proves to his own satisfaction that rabbits are *fattened and not poisoned* by the daily use of sulphite of lead! He, therefore, has something of a very original kind to communicate to the public and profession. Not so with Mr. R. Warrington, who occupies a sort of avuncular position in the case: this

gentleman, in a circular letter which has been widely published through the daily papers, carefully abstains from making any statements regarding his own experiments and results, but he adopts the very unusual course of mangling the chemical and medical reports, and, with the ingenuity of a special pleader, he reverses the facts, picks out the minimum in preference to the maximum quantities of lead, as telling more favourably for his clients, and proves, by a species of arithmetical legerdemain, that, while loaf-sugar of the common process contains lead, that of the patent process contains none; and further, that the bastards and treacle of the common process now universally consumed, contain twice as much lead as those saccharine products which have been actually procured by the use of lead-salts! The curious part of the case is, that he attempts to prove all this, not from any results of his own experiments, but from the facts and figures of Professors Thomson, Graham, and Hofmann. Either, therefore, these gentlemen are great bunglers in chemistry and dunces in arithmetic, or the scientific representative of pharmacy at Apothecaries' Hall has stumbled upon a mare's nest.

In another article we shall endeavour to ascertain which of these conclusions is the more probable.

THE ACTONIAN PRIZE OF THE ROYAL INSTITUTION.

WE again think it desirable to remind our readers that the next Actonian prize of £100 will be awarded, in the year 1851, to an Essay illustrative of the Wisdom and Beneficence of the Almighty on the Physiology of any one of the Senses (Hearing, Seeing, Tasting, Smelling, Feeling). Competitors for the prize are requested to send their Essays to the Royal Institution, on or before 10 o'clock, P.M., December 31st, 1850, addressed to the Secretary, and the adjudication will be made by the Managers on Monday, April 8th, 1851.

Reviews.

Synopsis of the Diastaltic Nervous System. By MARSHALL HALL, M.D., F.R.S.S. L. and E., Fellow of the Royal College of Physicians, Foreign Associate of the Academy of Medicine of Paris, &c. &c. 4to. pp. 100, with Illustrations. London. 1850.

Memoirs I. and II. on the Nervous System. By MARSHALL HALL, M.D., &c. 4to. pp. 113. London: Sherwood, Gilbert, and Piper. 1837.

OUR readers are familiar with the contents of the last of the two works above named, which comprises the early announcements of the facts and reasonings on which Dr. Hall founded what has hitherto been known as the "reflex theory." We shall therefore on the present occasion only bring it under notice as explanatory of the new terms proposed by the author in his "*Synopsis of the Diastaltic System.*"

In his preface to the latter work Dr. Hall observes:—

"To treat fully of the infinite number of topics which are here laid before the reader in mere outline would occupy a considerable volume; and for such a volume, in the present state of the profession, there would not be found readers; for 'monographs do not sell'—that is, are not read. The present cheap, elementary, and compilative state of medical literature will exclude for a time all original works. This *Synopsis* has been printed at my own expense. . . . Much more might be written upon this subject. The present has been too justly designated 'the age of medical degradation.' When members of our profession shall be really and fully imbued with all its literature, they and it will take the station which is due to them. But there are those who actually boast that they never read!—that is, that they are without science and without literature; that, for them, Prout and Liebig have laboured and written in vain! The result is, that our profession is indeed in a state of 'degradation!'"

There is much truth in these remarks of Dr. Hall. Compilations, manuals, &c., may be useful, even necessary; but compilers may take the place of, while they suppose themselves to be, original investigators and authors. But, as Dr. Hall truly adds, between the productions of such minds and those

of the minds of Harvey, Hunter, and Jenner, there is as much difference as there is between a painting of Raphael and an attempted copy. Whatever may be the ultimate fate of the "reflex" or "diastaltic" theory, there can be no doubt that Dr. Marshall Hall, has laboured in the spirit, and with the zeal and sincerity, of an original investigator.

We proceed to consider the peculiar or novel features of Dr. Hall's last publication. These consist almost entirely in the introduction of a new nomenclature. We extract the following passages as conveying its chief points:—

"On analysing the facts which have been detailed, I observed that the following anatomical relations are essential:—

"1. A nerve leading *from* the point or part irritated *to* and *into* the spinal marrow;

"2. The spinal marrow *itself*; and

"3. A nerve, or nerves, passing *out of*, or *from* the spinal marrow;—*all in essential relation or connection with each other.*

"On these anatomical facts I have ventured to institute a new nomenclature, descriptive of what I have hitherto designated the *spinal system*, and expressive of these essential points. The term *peristaltic* (from *περι* and *στρέλλω*, to contract) is familiar to us all. It may be justly extended to all the movements of the interior organs—as the heart, the stomach, the large and small intestines, the uterus, &c. These movements, it is well known, are independent of the spinal marrow. But it has been shown that a series of experimental phenomena—and it will be shown hereafter that a series of important functions—are effected by means of the series of nerves in essential connection with the spinal marrow to which I have adverted. The action is shown through the spinal marrow as its essential centre. I propose to designate the phenomena by the term *diastaltic*.

"The spinal system may henceforth be designated the *diastaltic nervous system*,—a designation which will have the advantage of including this system in the invertebrate, as well as the vertebrate, tribes of animals. This system embraces a peculiar anatomy, physiology, pathology, and therapeutics. Perhaps the only *purely* diastaltic function is *respiration*; and this is variously modified by volition, and influenced by emotion.

"We are much in need of other terms still to aid us in this investigation. The terms incident, excitor, and reflex motor, have been used to designate those nerves whose influence proceeds *to* and *from* the

spinal marrow. But they have *lity* and *appeared* to me satisfactory; and I *am* *wished* for others *more* expressive and explicit. The following compounds of *δῶς*, a way, have appeared to competent judges very appropriate to our subject:—*esodic* (*εσω*) will express the action *into*; *exodic* (*εξω*), the action *out of*; *anodic* (*ανω*) will express the *ascending*, *cathodic* (*κατω*) the *descending*, course of action; *pallodic* (*παλω*) and *panthodic* (*πανω*) will express the facts, on which I shall shortly have to dwell at considerable length, of the action of the *vis nervosa* from each *one* point of the diastaltic system, in *many*, or even *all* directions, to *every* other.

"Many important facts, many important truths, will be conveyed to the mind at once by these simple terms. Their root is already familiar to us in the word *periodic*; and several derivations from it have already been employed in the science of his creation, by the illustrious Faraday. It must be distinctly understood that they are *all* to be restricted to the anatomy, physiology, pathology, and therapeutics of the diastaltic nervous system, in which they express the modes of action of the *vis nervosa* distinctly from, and exclusive of, all other influences whatever—as sensation, volition, emotion, &c." (p. 4-6.)

Dr. Hall in the next place proceeds to detail experiments and demonstrations of his views in illustration of the new nomenclature. These, however, consist in great part of facts and experiments similar to those stated in his previous memoirs, which are well known to physiologists and pathologists, and the conclusions from which are disputed by many of the most eminent cultivators of that science. We shall, here, in justice to the author, present our readers with a brief abstract of Dr. Hall's statements on the anatomy and physiology of the diastaltic system.

Dr. Hall divides the nervous system into an *in-excitor* or *astaltic*, and an *excitor* or *staltic* portions. The former embraces the cerebrum and cerebellum, and the olfactory, the optic, and the acoustic nerves; the latter, the tubercula quadrigemina, and the new *class* of the *esodic* nerves, the spinal centre, and the *exodic* nerve, embracing the spinal nerves. The *in-excitor* portion is the seat of volition and of emotion, the latter approaching the excitor. Below the seat of emotion and passion, Dr. Hall places excitability and the diastaltic action; and evenly with these the peristaltic and secretory system, including the ganglionic system.

Anatomical views are set out in form by the author, and an ingenious mode of synthesis suggested, which shows the relations of different parts.

The physiology of the system the author represents as consisting in a series of arcs, formed of an esodic nerve, the spinal centre, and an exodic nerve, essentially linked together, and in diastaltic action. The appropriate stimulus of this action may be applied to any part of this arc, origin, centre, or termination. This position is illustrated by tabular statements of the diastaltic arcs of the iris, eyelid, respiration, larynx, deglutitious orifices and exits, ingestion, and egestion.

The exposition of the anatomy and physiology of the nervous system is followed by the consideration of the diastaltic theory to obstetrics and to pathology.

The views of Dr. Hall, as expounded in this volume, present much extremely interesting matter. They overlook too much, we think, the influence of the brain, and the intimate connection of different parts of the nervous system, by attributing all its phenomena to the spinal centre. The phenomena of disease and of mental emotion manifest a direct control to be exerted by the brain, which Dr. Hall's theory leaves unexplained.

In acknowledging the value of Dr. Marshall Hall's contributions to science, and admitting more especially the great degree of light that he has thrown on the functions of the spinal cord, we cannot refrain from expressing a wish that he could manifest a less quarulous and irritable disposition than is exhibited in the following extracts:—

"I will only add" (to an historical sketch), "in conclusion of these brief remarks, the expression of my regret that any of my professional brethren should be found of minds so ignoble as to persist in the injustice which has been so long, although vainly, attempted in this matter,—continually immolating, during the whole course of nearly twenty years, truth on the altar of misrepresentation and detraction."

In a foot-note to this passage the author names "Dr. Forbes's Review, Dr. Todd's Cyclopædia," &c.

In a pamphlet by Dr. Hall, "On the Neck as a Medical Region," which we

have before us, we meet with the following passage:—

"I am quite aware that neither the professional nor the public mind—they are, indeed, nearly on a par—are raised sufficiently for views so 'rational.' But then I do not write for the present day; and the day will come—and I shall promote its advent—when medicine will form a science, based on physiology, and calling in the aid both of theory and of observation."

Dean Swift wisely said, "It were chimerical to write for posterity, of whose tastes we cannot make any judgment, and whose applause we can never enjoy." If Dr. Hall be as anxious for the applause of posterity, as of his contemporaries, there can be little reason why he should fret under the scrutiny and hesitation with which his views have been received. It is natural that an original investigator should look upon his own labours with a partial eye; but he must know that all eyes have not the same point of view for every object; that other labourers may be at work in different parts of the same field; and lastly, he may remember that, even as regards himself, "*humanum est errare.*"

Contributions to the History, Diagnosis, and Treatment of Croup. By JOHN WARE, M.D. Pamphlet, 8vo. pp. 29. Boston, U.S. 1850.

THE author of this essay divides croup into four forms,—viz., membranous, inflammatory, spasmodic, and catarrhal,—thus treating as separate forms of one disease the different stages or degrees of severity of one or more distinct diseases. The descriptions, however, given of the several forms are accurately written, and would well serve as the basis of a different classification.

Dr. Ware warmly advocates Dr. Green's plan of applying a solution of nitrate of silver to the larynx.

We quote a few remarks on treatment, with which we in a great measure concur:—

"I am well satisfied, from what I have now seen of this method of treating croup, as compared with that which has been followed for so many years, that it has advantages which were pointed out in one of the preceding papers. It is a disease which I would treat without depletion, except perhaps a few leeches,—without vomiting, without purging, without blis-

tars, without antimonials, ipecac, and all those other nauseous remedies which have been usually resorted to. I would trust to opiates, perhaps calomel, emollients, and the local application of nitrate of silver."

Recherches sur l'Etat de la Contractilité et de la Sensibilité Electro-musculaires dans les Paralytiques du Membre supérieur, étudié à l'aide de la Galvanisation localisée. Par le Dr. DUCHENNE (de Boulogne). 8vo. pp. 39. Paris. 1850.

THE observations and deductions from the cases and experiments related in this pamphlet may be summed up in the following conclusions:—

When the electric force is limited to a single muscle, or single bundle of muscular fibres, the paralytic of the superior extremity arrange themselves in two classes. In one, the electro-muscular sensibility and contractility are diminished or entirely destroyed; in the other, the electro-muscular contractility is intact, and the electro-muscular sensibility is either normal, augmented, or diminished, and sometimes destroyed. In the first class are found paralysis from lead and from other lesions of the spinal marrow or spinal nerves; in the second, paralysis following on cerebral lesions, and rheumatic and hysterical paralysis.

1. Lead Palsy.

Certain muscles lose altogether the property of contracting under the stimulus of galvanism in the following successive order:—extensor communis digitorum, extensor indicis, extensor digiti minimi, extensor pollicis longus, extensores radiales, cubitales; abductor pollicis longus, triceps, and deltoid. This loss of power may affect any single muscle. Lesion of muscular contractility is usually accompanied with lesion of sensibility.

2. Palsy proceeding from Lesions of the Spinal Cord or Nerves.

In these cases the diminution of electro-muscular contractility is already observable towards the commencement of the second week.

The law laid down by Dr. Marshall Hall—"Irritability is diminished in spinal paralysis"—should be thus modified: lesions of the spinal marrow *almost always* produce loss or diminution

of electro-muscular contractility and sensibility.

3. Palsy following on Cerebral Lesions.

There is but little difference observed in the muscles in these cases.

4. Rheumatic Palsy.

The electro-muscular properties of the muscles are intact.

5. Hysterical Palsy.

The electro-muscular contractility of the muscles remains; their electro-muscular sensibility is diminished or destroyed.

A Manual of the Dissection of the Human Body. By LUTHER HOLDEN, F.R.C.S., Demonstrator of Anatomy at St. Bartholomew's Hospital. Part III. Small 8vo., p. 307 to 409. London: Hingley. 1850.

THE contents of this part of Mr. Holden's excellent practical manual are—the dissection of the abdomen, of the parts concerned in inguinal hernia, of the male perineum; a side view of the pelvic viscera in the male; structure of the bladder, prostate, &c.; dissection of the female perineum and pelvis; of the minute anatomy of the abdominal viscera; and the dissection of the lower extremity. These are all given clearly, and in as few words as will serve the purpose of the student. We can add our commendations of the present to those of the preceding portions of Mr. Holden's work.

A Treatise on the Climate and Meteorology of Madeira. By the late A. J. MASON, M.D., Inventor of Mason's Hygrometer. Edited by JAMES SHERRIDAN KNOWLES. To which are attached a *Review of the State of Agriculture, and of the Tenure of Land*, by GEORGE PEACOCK, D.D., F.R.S., &c. &c.; and an *Historical and Descriptive Account of the Island, and Guide to Visitors*, by JOHN DRIVER, Consul for Greece, Madeira. 8vo. pp. 888. London: Churchill. Liverpool: Deighton. 1850.

No pains have been spared by the friends of the late Dr. Mason, as will be seen from the names on the title-page of this work, to render this volume complete in its description of the climate of the island of Madeira. That the result has

been successful will be 'apparent' to all who consult the work. Tables and diagrams accompany the meteorological observations by Dr. Mason.

The entire volume constitutes an important contribution to climatology. The additions of Mr. Peacock and Mr. Driver contribute, we may state, very considerably to the character and completeness of the work. On every account we strongly commend it to the perusal as well of the general reader as of the visitor to Madeira.

Proceedings of Societies.

PATHOLOGICAL SOCIETY OF LONDON:

Oct. 15, 1860.

DR. LATHAM, PRESIDENT.

MR. CESAR HAWKINS related a case of *Strumous Disease of the Os Calcis, Femur, and Cranium, resembling Malignant growths*;

and exhibited two preparations from it of necrosis of the os calcis, in which the dead bone, infiltrated with pus, was still entirely connected with the living bone, although the disease had commenced eight years previous to its removal by amputation. The joints between the astragalus of the os calcis were partially ankylosed, and, although the astragalus itself was quite healthy, the joint between the astragalus and the tibia showed the commencement of ulceration of the cartilages; demonstrating, as Mr. Hawkins remarked, the manner in which the inflammation of the soft parts sometimes conveyed disease from one tarsal or carpal joint to another, making the removal of pieces of necrosed bone, or the excision of even an entire bone, not always successful. The case was remarkable, however, more from its history, as illustrative of the difficulty occasionally observed in distinguishing between scrofulous disease and malignant affections.

The patient, a young woman, was admitted into St. George's Hospital with a large phagedenic ulcer of the inside of the ankle, excessively painful, and requiring large quantities of opium for its relief, with much thickening of the soft parts, looking in the section not unlike scirrhus, and having in the centre some warty granulations, resembling the cancer of cicatrices (of which Mr. Hawkins has written a description), in the centre of which the probe

passed down into the joint between the astragalus and os calcis, without touching dead bone. After some attempts to heal these parts, amputation was proposed, but declined by the patient. After a few months a mass of glands formed low down, in the groin, as large as an orange, as if enlarged by the contamination from the apparent cancer below, which did not secrete like strumous glands, but which sloughed gradually away after previous ulceration of the skin; and as some were destroyed fresh masses formed by their side, which went through the same process of sloughing during two or three months. About the same time there formed at the lower part of the femur, on its inside, a firm elastic tumor, obviously connected with the periosteum, but without bony deposit, about four inches in length, and perhaps two inches in height; and soon after this a growth took place on the left side of the frontal bone, soft in the centre, and consisting apparently of a morbid growth in the diploe, making its way by pushing out the outer table, with a little absorption of the bone in the centre. Thus was formed a combination of appearances in every respect seeming to confirm the supposition of the malignant nature of the original disease, and quite sufficient to deter Mr. Hawkins from operation, which the woman was now desirous of. In two or three months more, however, and, as it seemed, chiefly from the use of iodide of potassium and sarcaparilla, all these latter growths disappeared; the tumor of the thigh gradually subsided, the glandular masses also sloughed out, and the part healed, the growth of the diploe went away, the bone recovered its former level, and the skin recovered from the sallow complexion it had assumed,—and amputation was performed. The patient was quite well a year and a half afterwards; and it is presumed, therefore, that the deceptive growths of the femur, and cranium, and glands, could not have been malignant, and perhaps not also the morbid texture in the ulcer of the foot. It seemed, therefore, not undeserving of the attention of the Society, in conjunction with the case about to be related by Mr. Hewett, in which a similar difficulty of diagnosis existed as to the strumous or malignant nature of the disease.

MR. PRESCOTT HEWETT presented a specimen of

Crude Tubercle in the Medullary Cavity of the Femur,

an affection which he considered to be a very rare one, more particularly in this country.

The preparation was taken from a man,

of about thirty years of age, who was admitted into St. George's Hospital a few years back with a tumor situated at the union of the middle to the lower third of the thigh, a careful examination of which proved that the disease was intimately connected with the bone, apparently springing from it, and occupying the greater part of its circumference. Somewhat globular in shape, this tumor was unyielding in its nature, but not painful when handled; its surface was generally smooth, and the circumference of the affected bone was larger in this part, by two inches, than that of the opposite one. The patient reported that, fifteen months previous to his admission into the hospital, he had, for the first time, begun to suffer considerable pain in the bone of a shooting character, which deprived him of rest; three months after this the swelling made its appearance, and gradually increased in size. At this time he also suffered from swelling and induration of the testicles, but this subsided, and then recurred once or twice, leaving the right testicle and chord somewhat enlarged and hard; his health had begun to fail about seven months after he was first attacked, and the pain in the thigh had, with few intermissions, been continual, and of a severe character. The countenance, which was anxious and sunken, was sallow; there was little or no appetite, and the general health was much broken. The prevalent opinion was that, in all probability, the disease about the thigh was of a malignant nature; no operation was proposed, the aspect of the case being too unfavourable; the patient was put upon sarsaparilla, and blue ointment was applied to the testis. In a few days the gums were affected, the countenance became very anxious, and the skin slightly jaundiced; he also now complained, for the first time, of great pain in the right hypochondriac region, where the liver was found to be much larger than usual, hard and very tender. Blisters were applied to the abdomen, the mercury was left off, and hydriodate of potash was ordered with the sarsaparilla. Under this treatment the general health began to improve; the hardness and swelling of the testis gradually disappeared; and in some little time the tumor of the thigh, when measured, was found to be less by an inch. These favourable symptoms continued steadily; and in a few months the man was made an out-patient, the hepatic symptoms being at that time but slightly marked, and the thigh presenting merely some general thickening of the bone at the part which had been affected. He was re-admitted the following year into the physician's wards for ascites; and while there was attacked with erysipelas, of which he died. At the

post-mortem examination extensive deposits of tubercular matter were found under the peritoneal covering of the right lobe of the liver, as well as in numerous parts of the sub-peritoneal cellular tissue generally. Similar deposits existed, also, in the structure of the kidneys, spleen, and lungs. On examining the parts which had been involved in the disease of the thigh, great thickening and condensation were observed about the cellular tissue uniting the muscles, and in that between the muscles and the bone; the periosteum, which was also very much thickened, presented on its free surface a large patch of tubercular matter enveloped in a dense cyst. The bone itself was irregular in shape, much hypertrophied, and very hard: at this part its medullary cavity was filled with tubercular matter surrounded by gray semi-transparent lymph, presenting very much the appearance of the well-known granule of the lung. No other bones were examined.

In addition to the rare occurrence of crude tubercle in bone, Mr. Hewett thought that the history of this case afforded a very good illustration of the great difficulties connected with the diagnosis of tumors affecting the osseous system. The more marked symptoms of the case certainly led to the supposition that the disease was of a carcinomatous nature; but this opinion was proved to have been erroneous by the disappearance of the tumor, which, in all probability, had been formed for the greater part by lymph effused around the tubercular matter found in the cellular tissue between the bone and the muscles.

Mr. ARNOTT exhibited a specimen of *Fracture of the Spinous Process of the Axis, with depression of the separated portion, death occurring one hour after the accident.*

A man, *æd.* 74, was admitted into the University Hospital July 13, 1850. He had for many years suffered much from pains in the head, and for which he had, at different times, been a patient of the hospital: they were described as most violent, recurring periodically, and were most relieved by immissions on the scalp; quinine, &c., being given without benefit. Twice he had suffered from symptoms of acute mania.

The day of the accident he had been occupied upon business of an anxious nature. On his return home he complained of feeling giddy, and immediately afterwards, on descending the stairs to the kitchen, he fell down to the bottom of the flight; when taken up was senseless and motionless, but soon recovered sufficiently to speak. He was admitted for this into

the hospital about forty minutes after the accident.

He complained of pain in the back of the head, on which was found a wound about half an inch long, and to its left a contusion of the scalp. No fissure was detected in the bone below the wound. He was sensible, but knew nothing of the accident; said he could not move his arms, and wished to be raised up; when either arm was raised up for him it dropped immediately, and he complained of no pain in them when pinched; he could move his lower extremities, when desired, with facility.

Right pupil moderately dilated, but acted freely; left eye diseased; pulse 90; breathing quiet; surface of body warm; complained of cold hands and feet, and desired them to be rubbed, though they were as warm as other parts of the body.

Blood in small quantities escaped from the mouth, which was not accounted for.

Soon after admission it became evident he was sinking, and he died twenty minutes after he came in.

Post-mortem examination.—No fracture of the skull; calvarium very thick and dense.

Dura mater.—Near the longitudinal sinus posteriorly were a few opaque patches. Glandulae Pacchioni not well marked; meningeal veins less turgid than usual. On dividing the dura mater on the left side about 3iss. of cere-sanguineous fluid escaped; the same on the right side, though less in quantity; the under surface of the dura mater pale, and covered with a layer of apparently recent lymph. On the left side the membrane was found much thickened over the lateral region, about two lines in thickness, extending upwards about one inch: this thickened part was divisible into two layers—the outer one of the thickness and consistence of the dura mater in other parts, the inner being thicker, of fibre-cartilaginous consistence, and above continuous with the arachnoid, where the opacity and thickness subside. Near the longitudinal fissure thin adhesions extend between the two layers of arachnoid. The longitudinal sinus contained a small clot posteriorly, and about 3ss. of dark fluid blood. The pia mater presented much fine ramiform and capilliform injection; the larger venous trunks rather turgid. On removing the membrane from the left hemisphere a small quantity of serum exuded, the surface of the brain presenting various amounts of punctiform injection; veins of the medulla congested; ventricles empty; choroid plexuses pale; commissures molles absent; fornix a little softer than natural. Weight of brain, 48 oz.; cerebellum, 5½ oz.

Neck.—On cutting down upon the cervical vertebrae, much blood was found extravasated between the muscles, especially between the oesophagi. On reaching the vertebrae, the spinous process of the axis was found broken off with a portion of its lamina, the posterior arch remaining entire. The broken-off spinous process was much depressed below the others, and wedged in between the arches of the axis and the vertebrae below it: possibly it had pressed on the cord; but, though the fractured edge nearest the cord was sharp, it had not injured the dura mater. The canal being exposed by the removal of the arches of the vertebrae, a considerable quantity of dark fluid blood escaped from the canal; and, as low as the sixth dorsal vertebra, blood was effused into the cellular tissue outside the dura mater. Around the origin of the nerves to the upper limb the amount was greater than elsewhere, the greatest being above the enlargement of the cord from whence these nerves are given off. The articulations between the axis and third cervical vertebra were very loose.

DR. PRACOCK exhibited

Two Specimens of Disease of the Heart.

1. One of these was an example of extensive aortic valvular disease. The specimen was from a boy, 18 years of age, who had been ill for nearly two years; and, during a considerable part of that time, had been a patient of Dr. Pracock's at the City Hospital for Diseases of the Chest. His illness was brought on by a sudden mental impression, which produced a fit, and was followed by symptoms of cardiac disease. In addition to the usual asthmatic symptoms, a loud murmur was heard with the systole of the heart, and this was followed by a feeble diastolic murmur. The murmur was most distinctly audible at the base of the heart, along the course of the upper part of the sternum, and on the right of that bone, and it was accompanied by a purring tremor, felt chiefly between the third and second, and the second and first right cartilages. The cardiac dullness on percussion was very greatly extended beyond its normal limits. The boy continued to be subject to fits of an epileptic character at intervals of two or three months, and he died suddenly. He had never had rheumatic fever, or any other serious disease before his seizure.

On examination, the heart was found of very large size, weighing 28 oz. avoirdupois. The hypertrophy and dilatation was very much confined to the left ventricle. The aortic valves, and especially the left and posterior folds, were extensively adherent at their angles of attachment and sides, and they

were also much thickened and indurated, so as to lessen the capacity of the aortic orifice. The anterior valve was studded with cretaceous vegetations, and was broken down so completely as to leave an aperture admitting the point of the little finger, by which a column of fluid freely regurgitated into the ventricle from the aorta. The aorta was much dilated in its ascending portion. The ventricular walls had undergone in places the fatty degeneration, and a small piece of bone was attached to the endocardium not far from the apex. The cavity at the apex was much expanded, and the walls were there very thin, and the endocardium much indurated.

2d. The second case was one of very advanced mitral valvular disease, removed from the body of a female, 39 years of age, who had suffered from two attacks of rheumatic fever within the last two years. She had been subject to palpitation and dyspnoea since the first attack, and had twice been a patient at the Hospital for Diseases of the Chest. She presented the usual symptoms of cardiac disease; and a loud murmur was heard with the systole of the ventricle,—most intensely at the apex, and then towards the left axilla.

On examination, the heart was found large, weighing 15½ ounces. The left auriculo-ventricular aperture was contracted to a mere chink, scarcely more than half an inch in length; and the folds of the mitral valve were thickened and rigid, and the cords much shortened.

Mr. TOYNSON exhibited a specimen of *Molluscum contagiosum* developed in the *External Auditory Meatus*.

The specimen was taken from a man, æt. 67, and the existence of the disease had not been observed during life. The tumor was about the size of a small nut, and occupied the posterior surface of the outer part of the meatus. The outer surface was of a pearl white colour, and shining. Upon being opened, the interior was found to consist entirely of epidermoid scales. The tumor projected backwards, had caused absorption of the layer of bone separating the mastoid cells from the meatus, and occupied a considerable portion of the mastoid cells.

Mr. AVERY presented a specimen of *Strangulated Femoral Hernia reduced en masse*.

The preparation was taken from the body of a woman, aged 60, who was brought into the Charing Cross Hospital on the 1st of September, 1850. Mr. Avery was absent from town when she was admitted, and did not see the case till the

post-mortem examination. Three days before her admission she had been seized with well-marked symptoms of strangulated femoral hernia, and was seen by a very intelligent practitioner, who persevered with the taxis until the swelling disappeared from the groin. He thought he had succeeded in returning the bowel safely into the abdomen; and the symptoms were considerably relieved at the time, and a free evacuation was procured by the aid of aperient medicines. Some few hours after, however, the pain and vomiting returned, and continued so obstinately that she was sent to the hospital. There she was treated with calomel and opium,—had leeches and fomentations, &c. applied to the abdomen. She gradually sank on the fifth day after her admission, passing from time to time fecal evacuations, which circumstance prevented any explorative operation being had recourse to, to ascertain the condition of the hernial sac.

On examination, the hernial sac, as large as a walnut, and containing a portion of small intestine firmly grasped by the neck, was found fairly pushed up, as raised, through the crural ring, and lay in the loose cellular tissue between that opening and the peritoneum. The neck of the sac did not embrace the entire circumference of the gut, which was proved by passing a director with care close to the mesentery, from the portion of intestine above the stricture into that portion below it. This latter circumstance accounted for the continuance of fecal evacuation, and deprived the poor woman of a fair chance which might have been afforded her by an explorative operation. Two or three inches of gut below the stricture were very dark, and bore the marks of constriction, and had been clearly contained in the sac a short time previously; probably, liberated at the time the sac was returned into the belly. At the bend of the thigh, in the situation the sac had occupied, there remained the condensed, cellular, and adipose covering, so well described by Mr. Luke, from which the sac had been separated. It was loose and flabby, as large as the end of the thumb, and had the appearance as if the hernial sac was still there. Mr. Luke, in his paper, has described five cases of reduction *en masse*, which he had seen; and my colleague, Mr. Hancock, has mentioned, in a recent work on Hernia, that out of eighty-four cases where the bowel was returned unsuccessfully, forty-four were of this character. It offers another instance where the operation external to the sac would probably have failed.

There was slight effusion into the cavity of the peritoneum; but the marks of peritonitis, and injury to the coats of the

bowel, were not considerable, and she seems to have sunk from exhaustion.

Dr. BRITH, R.N., presented a very interesting specimen of

Diseased Bladder and Dilated Ureter, with Calculi impacted in the latter.

A man, *et.* 53, had an attack of hemiplegia sixteen years ago, from which he never perfectly recovered. Three or four years ago he suffered from stricture of the urethra, for which he applied for relief; and in May last was attacked with hæmaturia and pus in the urine. Since that time has suffered almost constant pain in the hypogastrium and perineum, which occasionally assumed a violent paroxysmal form, accompanied with difficult and painful micturition. The urine alkaline, and loaded with pus and mucus, occasionally with blood. He died October 10th, having been in no way relieved by treatment.

Post-mortem examination.—The right kidney was converted into a large cyst four or five times the size of the healthy organ. It was filled with thick green fluid; from it there was a large opening passing down to the ureter. This latter tube was also considerably dilated, and its coats much thickened. Its lower opening into the bladder was entirely obliterated, so that the contents of the cyst and the ureter could not escape. The inner surface of both the cyst and the ureter was rendered uneven and irregular by numerous bands passing round portions of the walls, and constricting the cavities at these points. In the ureter this occurred to such an extent that it might be said to be divided into several compartments, one above the other. In the compartments three calculi were found imbedded, the largest of which occupied its superior third, and was about three inches long and three-quarters of an inch in diameter. The left kidney was about three times its natural size, but healthy in structure. The coats of the bladder were much thickened, and its cavity considerably smaller than usual. Its inner surface was studded with phosphatic deposits, and near its fundus was a fungoid mass as large as the palm of the hand. Examined microscopically, this mass was found to consist of triangular, oval, and other cells of a very irregular shape, resembling those found in malignant disease. The cerebellum presented a singular appearance; it was tough and indurated, and appeared to have been converted into a fibrous structure. The whole had an uniform straw colour, the appearance of the *arbor vitæ* being nearly obliterated. The brain otherwise was healthy.

Dr. JAS. EADON BISHOP exhibited a specimen of

Cancerous Disease of the Omentum, Mesentery, Pleura, &c.

A man, *et.* 60, of temperate habits, and who had enjoyed good health, was admitted into St. Thomas's Hospital, under his care, with symptoms of ascites and a chronic ill-conditioned ulcer, involving the ball of the great toe. He died five weeks after his admission, having suffered chiefly from dyspnoea when in the recumbent posture.

On examination, the abdominal cavity was found distended, partly by serous effusions, but chiefly by a large floating mass consisting of the enlarged omentum. The mass had a lobulated character, and consisted of clusters of smaller masses, the separate portions of which had, at first sight, very much the appearance of fatty nodules, resembling the appendices epiploicæ; but on cutting into them they presented a medullary appearance and consistence, and, when examined under the microscope, were found to be composed of globular, distinctly nucleated cells, intermingled with fatty matter. The mesentery was similarly affected throughout. The right pleural cavity was filled with clear serous fluid, by which the whole lung was compressed against the spine. Scattered over the serous membrane there were a number of small, grayish, lymph-like masses, which, on examination, were found to be of precisely the same character as the clustered masses in the abdomen. The bronchial glands, and the tissue of the lung itself, were healthy; and the left pleural cavity presented nothing abnormal: the liver was somewhat enlarged, and of a pale waxy appearance. The disease of the toe appeared to be also cancerous; and if this was the origin of the disease, it was worthy of remark that none of the abdominal glands were much, if at all, involved in the disease.

MEDICAL SOCIETY OF LONDON.

Oct. 26, 1850.

Dr. J. R. BENNETT, PRESIDENT.

Enormous Fatty Tumor.

THE tumor, which weighed fifteen pounds, was exhibited by Mr. HAYNES WALTON. Its great size rendered it remarkable. The man from whom it was removed was aged fifty; he had acquired notoriety from having been the inmate of several hospitals, to which he had resorted for its removal, but he always left before the intended operation. Just twenty years ago he observed the first

traces of its growth. He applied to him (Mr. Walton) in March of this present year, and begged him to remove it. At the time he had a slight cough, and was getting thin. His chest having been examined, it was suspected that he was suffering incipient disease of the left lung. He subsequently much improved, and his cough left him; and he begged of Mr. Walton to operate. After a consultation, it was determined that an operation was justifiable. There did not appear to be the development of any disease that forbade it—an opinion which had been expressed at all the hospitals to which he had applied. The operation was performed on the 21st of July, in the presence of several surgeons. The cast exhibited was taken a few days before the operation, and was a correct representation of it. It showed the tumor to be of great size, of a quadrilateral form; its situation was on the right lumbar and gluteal regions; its base measured three feet.

In the operation, the integuments were divided by two transverse incisions and a vertical one. The investing capsule was peculiarly dense, and so adherent to the tumor that not a particle of the connection could be torn through, but required to be carefully dissected, especially as strong septa passed between and tightly embraced the small lobes that covered its surface. A considerable quantity of blood was lost, not from arteries that fed it, for they were small and quickly tied, but from the emptying of the blood that was contained in the fatty mass. He was very low for several hours after the operation, but rallied wonderfully by the next day. The density of the capsule, its firm adhesion, the hardness of the fat, and the vascularity, were peculiarities, some or all of which might have been due to the many irritating substances that had been applied to it for years with the view of dispelling it.

On certain Affections of the Nervous System simulating Chorea. By Mr. PILCHER.

CASE I.—In August 1847, Mr. Pilcher saw a young man, aged twenty, in Berkshire, born of healthy parents, and living in a healthy district, who was affected with slight erratic movements of the upper limbs and face. There was also, apparently, extreme dyspnoea; the breathing was stertorous, and inspiration appeared to require the most laborious exertion of the muscles; expiration was less laborious. This had lasted for several months, without interruption, except during sleep. Walking was very difficult, though the patient could keep himself erect with very little assistance. He was treated in various institutions, and had now in a great measure recovered,—the following being his condition on October

20th, 1850:—The bowels, urine, and appetite were all well; sleep good; pulse rather quick; face flushed; he blushed easily, and considered himself very nervous. No cause could be assigned for the affection.

CASE II.—Mr. J. M., a respectable tradesman of Christchurch, in 1837, had a severe attack of bilious fever; and, in the next year, had occasional very slight "unpleasant" feelings in his head, when sitting in a confined posture. Two years after this, the feeling had become more intense; he could not sit at ease without putting his hand to his head, though without being able to assign a reason. After this, when he was sitting in a confined posture, the head would "give a sudden snatch" to the left side; and this was always prevented when he was able to keep his hands applied to his head. In 1842 the affection had become much more severe, but frequently did not occur when the patient most feared it. Various kinds of treatment—leeches, aperients, iron, nitrate of silver, electricity, &c.—had been tried; but with at most only temporary success, and the disease still continued unabated up to the present time. It was mitigated in severity by mild tonics and occasional aperients; and increased by nervous excitement, powerful purgatives, and depletion. There was an elevation of the right shoulder, with fulness over the right scapula; probably arising from the excessive action of the muscles of that side, especially the trapezius. The trapezius and sterno-mastoid muscles of the left side appeared partially paralyzed. The patient had felt no pain in the head or neck. Two analogous cases, in females, furnished to Mr. Pilcher by Dr. Davies, were also read. The patients had recovered under tonic treatment.

Mr. Pilcher believed that ordinary chorea was an affection of the excitomotor system, and mostly produced by eccentric irritation; but, in the cases now related no eccentric cause could be assigned: the disease seemed essentially functional. He compared the choreic affection, to a certain extent, with the hysterical affection of joints, described by Sir B. Brodie; the alliance appearing to exist in the disorders being similar in character, commencing in the brain, but affecting different parts of the nervous system; the sensory nerves being affected in one series of cases, and those of volition in another. That they were cerebral or mental affections, seems proved by their occurrence in persons of weak mind, or whose intellects, naturally powerful, had been overworked; and by the success obtained by renovating the mind, either through the medium of the body, or by directing it to more healthy occupations.

The tenderness of the spine had been observed by Mr. Filcher in the first two cases, nor could any mental cause be assigned.

ACADEMY OF MEDICINE, PARIS.

Oct. 22, 1880.

Arsenic and Adansonias digitata in Intermittent Fever.

DR. BERNIER stated that he had employed arsenic in chronic cases of ague attended with enlarged spleen, very successfully: cases that had resisted quinine had yielded to two or three doses of arsenic.

M. BOUVIER, in the name of M. Chatin, related several instances of the exhibition of the adansonias in intermittent fever, by which it was shown to have completely failed.

The Employment of Zinc in Painting regarded in a Hygienic Point of View.

M. BOUCHUT stated, as the result of his researches, that since the employment of zinc in painting is not attended with any of the evil effects which follow the use of white-lead, it should officially supersede the latter metal.

Iodine Vapour in Phthisis.

M. CHARTROULE read an essay on the use of iodine vapours, in which he attributed to this mode of the exhibition of iodine a superiority over other modes or forms of its combination.

BIOLOGICAL SOCIETY OF PARIS.

Monthly Summary, August 1880.

New Researches on Contractions of the Skin under the Stimulus of Galvanism. By M. BROWN-SEQUARD.

THE following conclusions are stated by M. Brown-Sequard in reference to the opinion of Kölliker that the *cutis anserina* is only produced by galvanism within a circumference of from half an inch to an inch; while M. Sequard had stated that it might be produced over an entire limb. The difference in opinion is explicable by the experiments of Kölliker having been performed with moist instead of dry conductors, as used by M. Brown-Sequard.

1. *Cateris paribus*, contraction of the skin is more distinct and extensive in proportion to the force of the galvanic current.

2. The conductors should be dry, or the current is readily conducted to subjacent structure.

The experiments of M. Brown-Sequard lead him to the conclusion that the contraction of the skin takes place from the action of the galvanic stimulus on its contractile fibres, and not through the medium of the nerves of the integuments.

Deranged Nutrition of the Eye consequent on a Lateral Section of Half the Spinal Marrow in the Dorsal Region. By the same.

Everybody, M. Brown-Sequard remarks, is familiar with the consequences to the eye, of section of the fifth pair of nerves within the cranium, or of removal of the superior cervical ganglion; the effects of worms in the intestines also, and of certain affections of the spinal cord in producing derangement of vision, and even amaurosis, are well known. M. Brown-Sequard observed analogous effects ensue in four out of nine cases where he had divided the lateral halves of the spinal marrow at the tenth, eleventh, or twelfth dorsal vertebra, in guinea-pigs, the morbid conditions being observed to follow on the side corresponding to the lesion.

M. Brown-Sequard has never seen similar effects follow, in both eyes, the complete division of the cord.

Microscopical Examination of Alkaline Urates from a Tarsal Articulation. By M. ROUGET.

The specimen was taken from the body of a woman, forty years of age, appropriated for dissection. The urate was found to be deposited in cells analogous to the cells of the pavement epithelium lining the synovial membrane. From this examination M. Rouget inferred the manner of the formation of this deposit, that it was a change in the secretion of the synovial membrane: the cells, being filled with the alkaline urate instead of being re-absorbed, and constituting, by accumulation and absorption of the fluid parts, the concretion known as tophus.

Researches on Human Gestation.

M. COSTE read an essay, in which he stated the results of his examinations of the bodies of women dying suddenly from violence, or by suicide, at different periods of gestation.

In the bodies of all women dying suddenly during or immediately after menstruation, examined by M. Coste, he has found the uterus lined by so thick a mucous membrane that, if its constancy had

not proved it to be normal, it must have been regarded as a morbid product. This membrane was formed of glandules having orifices for the most part visible to the naked eye. In thickness it was equal to a fourth or a third of the muscular substance, and, in some instances, presented convolutions or folds pressed one against the other. In extra-uterine pregnancies this mucous membrane was thicker, and its convolutions as large as those of the cerebral surface, having a breadth not less than ten millimetres (= 1 centimetre, or .393 Eng. in.) From these facts M. Coste considered it demonstrated that every time an ovum arrives at maturity in, or is detached from the ovary of a woman, the uterine mucous membrane undergoes a change to prepare for its reception.

M. Coste has also examined the Fallopian tubes with a view to ascertaining whether in the pregnant state these remain free and pervious, or whether their uterine orifices become closed by a membrane which is to form the decidua. The result of his researches lead him to assert that their orifices remain open, and that the ovum falls into the cavity of the uterus, unless any abnormal cause obstructs its descent.

The changes which the ovum, &c. then undergo were thus stated by M. Coste:—

From the twentieth to the thirtieth day after conception the uterine orifices of the tubes communicate freely with the cavity of the uterus, the mucous membrane is thickened. The ovum, instead of being free in the uterine cavity, is buried in the mucous membrane; so that, on first opening the uterus, the existence of pregnancy might be doubted. Consequently, M. Coste considers that normal pregnancy may be said to be at first, interstitial growth. The ovum continues progressively enlarging, distending its covering of hypertrophied membrane; this distension going on, the ovum sensibly protrudes into the uterine cavity, attached by its opposite aspect to the base of the mucous membrane. The projecting portion becomes what anatomists have named the reflected decidua; that portion which remains attached to the muscular surface becoming the placental decidua; the rest of the mucous covering of the ovum becomes its parietal or uterine decidua. These three deciduas possess the same organisation as the mucous membrane whence they are derived, and it is only by the progress of development that they lose this character.

It is not, then, necessary, M. Coste remarked, to have recourse to the pseudo-membrane of Hunter, in order to explain the formation of these parts of the decidua: the development of the mucous membrane

of the uterus is sufficient to explain the phenomenon. If these portions of the decidua be but modified mucous membrane, they should be cast off after delivery,—and this is precisely what occurs; and the mucous membrane of the uterus is regenerated after all the debris of the decidua have been cast off with the lochial discharge.

This explanation of the nature of the mucous covering of the ovum, M. Coste considered, throws much light on certain otherwise obscure phenomena—*e. g.*, post-partum hemorrhages, the lochia, the propagation of puerperal inflammation by infection, and certain irremediable forms of sterility.

The Formation of Sugar in the Liver.

M. CL. BERNARD read an essay in which, after referring to the experiments of Magendie and other physiologists, which demonstrated the existence, sometimes, of sugar in the blood and other animal fluids; regarded by them as accidental and dependent on the nature of the food; it was shown that the presence of sugar in animal organisms is constant, and indispensable to the performance of certain regular functions; that the production of sugar is a constant and special function of the liver; that this function is under the immediate control of the nervous system; and lastly, that the blood which flows from the liver into the sub-hepatic veins invariably contains sugar in man and animals, whatever may be the nature of their aliment.

Nervous System of Insects.

A memoir was read by M. FELIX DUJARDIN, in which the following propositions were stated:—1. That in certain articulate animals a true brain exists, proportionate in structure and size to the intellectual manifestations. 2. That the brain or sub-oesophageal ganglion contains complex, symmetrical, pedunculated bodies, which vary in size according as intellect or instinct predominates. 3. The same pulpy substance of which these pedunculated bodies consist, is found exclusively to constitute the thoracic and abdominal ganglia that regulate and combine the instinctive actions.

LEGACY TO KING'S COLLEGE HOSPITAL.

THE treasurer of King's College Hospital has received the handsome legacy of £500 from the late James Bailey, Esq., and a further sum of £200 from the executors of the late W. J. Frodsham, Esq.; forming, together, a very seasonable assistance to an institution depending entirely upon voluntary bounty, and having so many demands upon its resources.

Hospital and Emancipation Reports.

KING'S COLLEGE HOSPITAL.

Stricture impassable to instruments—complicated with Perineal Fistula—Perineal Section.

A SHORT time since we reported an interesting case of stricture of the urethra, which was complicated by perineal fistula and by calculus, and where it was necessary to perform the operation of external section. Shortly after this patient had been dismissed from the hospital, another inveterate and intractable case of stricture presented itself, and was treated in a somewhat similar manner, and with the greatest success; and as the subject of treatment of stricture by external incision has of late been productive of much discussion amongst surgical authorities, we shall give an account of this case, and make some further remarks upon it.

The patient, a man about forty years of age, was admitted into King's College Hospital, under the care of Mr. Fergusson, in the middle of June last. The immediate cause of his admission was the fact of an immense swelling of the scrotum having suddenly taken place; he laboured also under sharp irritative fever, and he had great difficulty in urination. His history previous to this attack was as follows:—

When a young man he had gonorrhoea, and about seven years ago he first began to feel the symptoms of stricture. As year by year advanced he felt these symptoms increase, and the difficulty in passing his water became more marked. About fifteen months ago, effusion of urine took place suddenly, and he was taken to one of the London hospitals, where incisions were made in the perineum; and the patient recovered from this attack. Whilst he was under treatment in this hospital, no attempt was made to pass a catheter until three weeks had elapsed, at which period chloroform was given him and an instrument was passed, but he did not remain sufficiently long in the hospital to gain any permanent relief. A fistula remained where the opening had been made in the perineum, and this did not close. At the end of nine months this patient was admitted again into the same hospital, as the symptoms of stricture continued to be aggravated. A decided attempt was now commenced for the cure of this stricture by dilatation: an instrument of considerable size, according to the patient's own account, was passed into the bladder and retained there for the space of twenty days, when it was extracted;

but in the extraction there was great difficulty, as the end of the instrument had become thickly encrusted with phosphates, which, in the words of the patient, "looked just like an oyster shell." This operation gave the man excessive pain; and in all probability the urethra was much lacerated, as, on the next attempt to pass an instrument, only one of a very small size could be passed. Upon this the patient left the hospital again and returned to his work, and continued at it until the commencement of June, when suddenly one day he noticed that his scrotum had become greatly swollen. Upon this he sought admission into King's College Hospital.

On examination, it was discovered that the scrotum was immensely swollen and distended with some fluid. When a catheter was attempted to be passed, none could enter into the bladder, and there was a fistulous opening in the perineum. A free incision was made into the distended parts, and a large quantity of matter mixed with foetid urine was evacuated, to the great relief of the patient, who quickly rallied from the irritation which had been produced. It was now advisable to attempt to dilate the urethra, and Mr. Fergusson examined the patient with a catheter, but found it stopped at the bulb by a very tough stricture, which would not allow the smallest instrument to pass. Several attempts were made in the same manner to get a passage into the bladder, but none of them succeeded; consequently Mr. Fergusson determined to open up the perineum, and divide the stricture by free external incisions. This he was the more inclined to do as there was excessive irritability of the urethral canal, and there was great induration of the tissues of the perineum.

On Saturday, July 6, Mr. Fergusson performed the operation in the following manner:—The patient being put under the influence of chloroform, a catheter was passed down to the seat of stricture; a free incision was then made through the indurated tissues in the centre of the perineum down upon the urethra, and the point of the catheter was reached. The knife was now carried further along, and the whole extent of the strictured part was divided, until the surgeon was enabled to pass an instrument fairly into the bladder. There was no particular amount of bleeding, and no more difficulty in the operation than usual. The patient was placed in bed, and a gum-elastic catheter was retained in his bladder.

8th.—This patient has not had a bad symptom since the operation, and has suffered only the ordinary amount of sympathetic fever; pulse is 98, tongue clean; the catheter is producing no irritation, and the water passes freely away through it.

13th.—The catheter has been producing some amount of irritation; it was, in consequence, taken out of the bladder; but there was some little difficulty in withdrawing it, as its extremity was entangled with phosphatic deposits. Mr. Ferguson introduced another instrument, and ordered it to be retained.

16th.—Mr. Ferguson to-day introduced a No. 12 catheter into the bladder with ease. The wound is looking well, and is granulating in a most healthy manner; the patient is improving rapidly in his health; appetite is good, tongue clean, pulse good, and he is recovering fast. The catheter which was last passed could only be retained two or three days, as it produced considerable oedema of the prepuce; it was accordingly extracted, and the parts were allowed to remain perfectly quiet, and no other instrument was introduced. After this the wound rapidly healed. On the 22nd no water at all was coming through the perineal opening, and he could pass it along the urethra in a full stream. Everything continued going on well with this patient: an instrument of full size was introduced along the urethra once or twice more, and he was dismissed well in the middle of August.

This case presents, in many respects, features of interest, and especially as lately there has been considerable discussion as to the line of treatment which should be adopted in certain cases of inveterate stricture which will not yield to ordinary measures. Surgeons of all ages, and of every school in this country, have recommended that those cases which will allow of their removal by dilatation alone should be treated by the catheter; and the majority of cases which we have to contend with, either in hospital or private practice, are of this nature,—that is to say, in by far the greater number of cases of stricture of the urethra, a temporary cure, at least, can be brought about by the cautious employment of dilating force. But hitherto the most experienced and careful surgeons have now and then met with such obstinate cases of stricture—cases not only obstinate, but complicated to such a degree, either in consequence of their situation or extent, that they have found it absolutely necessary to resort to stronger measures than those afforded by the use of the catheter or bougie. Thus every now and then the surgeon meets with a stricture involving the orifice of the urethra or extending some way within it. In such an instance it is almost useless to attempt a cure by dilatation alone; the readiest way is to divide the stricture by a cutting instrument, and then to apply a dilating power subsequently:

by this means a cure will be rapidly brought about by an exceedingly simple operation.

Then, again, there are a class of cases which are most troublesome to treat, and which are likely to lead to the most disastrous results to the patient, if some permanent relief is not given; and they generally, if not attended to, go on to such an extent, that it is found needful to lay aside the bougie, and to employ the knife. The early history of the present patient is an instance of this. A stricture is met with, and forms about the bend of the urethra. No care is taken about it; the person indulges in his usual habits: year to year is passed in this manner; the obstruction increases in severity and extent; and, if application is made to a surgeon, in all probability no instrument can be passed through the stricture, either in consequence of its extent and hardness, or from the circumstances of the urethra being in a most irritable condition. Under such circumstances there is constant danger of the urethra giving way behind the strictured part; in consequence of the straining efforts the patient feels compelled to make. This does happen suddenly, and he is either carried off, or, by timely interference, he rallies; but a fistulous opening remains in his perineum, and, as an outlet is thus produced for the urine, some relief is obtained; the patient again goes about his occupation without attending to the disease. The continual trickling of the urine through the fistulous opening produces a chronic inflammation and thickening of the tissues of the perineum; the urethral canal becomes more and more obstructed, and at last the condition of the patient becomes so bad that he is obliged to seek relief.

In some of these cases, if there be no particular urgency of symptoms, and if the obstructed portion of the urethra is not very extensive, and there be not very great induration of the tissues of the perineum, an entrance may be obtained into the bladder by the catheter, if both surgeon and patient persevere for a sufficient period. And when this is effected, and the urethra has become fully dilated, the fistulous sinusses will close up, and all the bad symptoms resulting from the obstruction of the canal, and from the unnatural course which the urine had been taking, will disappear.

But, in some of these cases, matters have become so bad, that recourse must be had to some more powerful agent than the catheter. In consequence of ulceration having taken place behind the stricture, extravasation of urine occurs, and places the patient's life in jeopardy: if he recovers from the first attack, and yet no instrument has been got into the bladder, or the case

has been neglected, he is liable to its recurrence, as in the case of the patient just narrated. On two occasions this serious accident took place; and, on the last at least, an enormous quantity of pus and urine was evacuated by the surgeon. As the patient, therefore, had already suffered so much, and as all the evil consequences of neglected stricture had developed themselves, and, after careful attempts, it was found impossible to get an instrument into the bladder by fair and gentle catheterism, Mr. Ferguson considered it a proper case in which to perform the operation of external incision. He had had several instances in the hospital of a somewhat similar nature, when the operation had been followed by the most perfect success. The same good result fortunately took place in this instance. In a short time the urethra had become fully dilated, and the patient left the hospital entirely free from every vestige of the troublesome malady which had annoyed him for so long a time.

This case, together with the one we reported in this journal some time since, will probably excite some interest at this time, as there has of late been a free, and somewhat angry, discussion amongst certain parties respecting the propriety of cutting strictures at all. Some eminent authorities, and one in particular—Mr. Syme, of Edinburgh, have distinctly affirmed that the division of a stricture at the point of the catheter, in such a case as here narrated, is never necessary, and, in fact, is an unwarrantable proceeding on the part of the surgeon. These gentlemen state that no stricture is truly impermeable, and that, with sufficient patience, a surgeon may always get a passage into the bladder. We are by no means disposed to deny this assertion; we believe that a metallic instrument may, by a sufficient amount of force, be carried through into the bladder, however firm the stricture may be. There are others, again, who advise somewhat freely the external division of strictures; and it must be confessed that surgeons of the greatest eminence, from Le Dran down to the distinguished Liston, have carried this doctrine into practice in such cases as were deemed proper for such operation.

We have now had an opportunity which perhaps has not fallen to the lot of very many, of observing with accuracy and care the effects of the treatment of stricture by perineal section; and we are now fully impressed with the conviction that neither the one doctrine, that strictures ought never to be cut, nor the other, that perineal section is frequently necessary, and should be unsparringly carried into practice,—is either correct or safe to act upon. We have now seen several cases in which the patient was

brought into such a state of misery and danger, and the difficulties in the ordinary treatment were such, that it was found absolutely necessary to resort to the perineal section; and the operation has been followed, as we have before stated, by such excellent results, that any surgeon who would call such practice unwarrantable would either show great prejudice or want of experience. On the other hand, again, we have seen death resulting from the division of the urethra, even in cases where there has been but little difficulty in the operation; and this has happened in instances where it was by no means absolutely necessary to perform perineal section. In one case death resulted ten days after the operation which had been performed, when even a moderate-sized catheter could be passed into the bladder—an unconquerable argument against the performance of perineal incision in cases where a catheter can be previously passed into the bladder, as recommended by Mr. Syme.

As, then, it is found that death does occur after division of a stricture by external section, the surgeon is in duty bound to weigh all the circumstances of any particular case well before he puts this proceeding in force; and we are of opinion that in no instance whatever should the operation of perineal section be performed unless the most careful attempts have been previously made to introduce the catheter, or unless the patient be either in danger, or is particularly anxious to undergo it. In such a case as we have narrated above, the surgeon is perfectly justified in attempting to make a complete cure of the disease when he finds other means fail; and it will be, for the most part, found that the greatest success after operation ensues in those very cases which present the greatest difficulty, and where the disease has been of long standing, and great disorganisation of the tissues of the perineum and scrotum has occurred; for in such cases the system has, as it were, become accustomed to the irritation which has been constantly kept up, and it will be the better able to bear an operation. But in instances where there has been disease of a milder character, or of shorter duration, the system has not yet accustomed itself to constitutional irritation; and if a serious operation, as cutting through the perineum into the urethra, be performed, it will readily take alarm, and such excitement will be produced as will be sufficient to carry the patient off. Such, at least, has been the result of our own observation, after watching nearly twenty cases in which perineal section has been performed.

We believe, then, that the safest and most humane part to take in this much

discussed matter is to steer a middle course, and to act according to particular circumstances—to operate only in the worst cases, which will yield to no ordinary measures, and by no means to fly hastily to the knife when there is no actual necessity for it.

As for the proposal of Mr. Syme, to cut patients for stricture when an instrument can be already passed into the bladder, we confess it must be looked upon as a proceeding by no means justifiable, except on the urgent demand of the patient himself. We know of instances where fatal results have occurred after this proceeding, and others have been related where it was not only not attended with any good result, but where patients have been rendered worse, in consequence of the non-closure of the opening made during operation, and, of necessity, the existence of a perineal fistula. It appears that even in Edinburgh this method of treating permeable strictures has been denounced, and by a no less eminent surgeon than Professor Lisart, whose great experience and practical knowledge give great weight to any opinion he may express on so important a matter as the one under notice.

Medical Intelligence.

UNIVERSITY OF LONDON.

M.B. SECOND EXAMINATION.—1850.

Monday, November 4th.—Morning, 10 to 1.

Physiology.

Examiner, DR. CARPENTER.

1. In what does the process of *Digestion* essentially consist; what share in it is performed by the Salivary, Gastric, Pancreatic, and Hepatic Secretions respectively; and what are the results of its operation upon different kinds of alimentary material?

2. Compare the Physiological condition of Reptiles, Birds, and Mammals, as regards the relative activity of their *Circulatory* and *Respiratory* functions, and the influence of this activity upon the production of Heat and the general train of the Vital operations; and describe the mechanism concerned in each case.

3. What are the nerves concerned in the act of *Deplutition*; and what are the inferences you might draw from the circumstances under which that act may be performed (as shown in states of Disease, and by Experimental inquiries) with regard to the nature of Reflex action in general?

4. Compare the structure of the Com-

pound eye of the *Insect* with the Single Eye of *Man*, and show how each of them becomes subservient, as an optical instrument, to the reception of visual impressions: point out, also, the share which the *Mind* has in the ordinary exercise of the Visual Sense, and state how this may be proved.

5. What is the nature of the *Muscular Sense*; and what share does it take in the performance of Voluntary Movements?

6. Describe the successive modes in which the *Human Fetus* derives nourishment from its parent; and mention at what stages in the evolution of this plan it is checked in Fishes, Reptiles, Birds, and the inferior Mammalia.

Afternoon, 3 to 6.

General Pathology, General Therapeutics, and Hygiene.

Celeus de Re Medica.

Examiners, DR. BILLING and DR. TWEEDIE.

1. Explain what is comprehended under the expression *physical diagnosis*, as applied to the investigation of diseases.

2. Give an outline of the principles on which the treatment of spontaneous hemorrhages should be conducted.

3. When there is predisposition to gout or rheumatism (hereditary or acquired), sketch the hygienic rules you would recommend with a view to prophylaxis.

4. Translate the following passage into English:—

De fritione verò adeo multa Asclepiades, tanquam inventor ejus, posuit in eo volumine quod "communium auxiliorum" inscripsit, ut quum trium tantum faceret mentionem, hujus et aquæ et gestationis, tamen maximam partem in hæc consumpsit. Oportet autem neque recentiores viros in his fraudare, quæ vel repererunt vel rectè secuti sunt; et tamen ea quæ apud antiquiores aliquos posita sunt, auctoribus suis reddere. Neque dubitari potest, quin latius quidem et dilucidius, ubi et quomodo frictione utendum esset, Asclepiades præcepit; nihil tamen reperit, quod non à vetustissimo auctore Hippocrate paucis verbis comprehensum sit: qui dixit, "Frictione, si vehemens sit, durari corpus; si lenis, molliiri; si multa, minui: si modica, impleri." Sequitur ergo, ut tam utendum sit, quum aut adstringendum corpus sit quod hebes est; aut molliendum quod induruit; aut digerendum in eo quod copia nocet; aut alendum id quod tenuis et infirmum est. Quæ tamen species si quis curiosius æstimet, quod jam ad medicum non pertinet, facile intelliget omnes ex una causâ pendere, quæ demit. Nam et adstringitur aliquid, eo dampno, quod interpositum, ut id laxaretur, effecerat; et mol-

litur, ea detractis quod duritiam creabat: et implemus. Non ipsa, frictione, sed et cibo quipostea inquantum, cutem digestionem quidam relaxatam penetrat. Diversarum vero rerum in modo causa, est.

PASS EXAMINATION.

Tuesday, November 5.—Morning, 10 to 1.

Surgery.

Examiners, Sir STEPHEN HARRISON and Mr. HODGSON.

1. Name the different forms of Erysipelas: describe the appearances, symptoms, and progress, of Phlegmonous Erysipelas: state the most frequent causes of that disease, also its pathology: mention the principal modes of treatment which are employed, and state those which you should adopt.

2. Give the various dislocations of the Shoulder-joint, with the method of reducing each variety; and, in case of being unsuccessful in your first attempt, state the means to be pursued to secure a more fortunate result of other trials.

3. What is a Femoral Hernia? Describe the symptoms and treatment of a Femoral Hernia when in a strangulated state; and, when an operation is required, give the method of performing it, with the subsequent management of the case up to a favourable or any other termination.

M.B. SECOND EXAMINATION.—1850.

Afternoon, 3 to 6.

Medicine.

Examiners, Dr. BILLING and Dr. TWEDDIE.

1. Describe the local phenomena and terminations of inflammation.

2. Give a definition of purpura. Enumerate its varieties, and sketch the progress and treatment of purpura hemorrhagica.

3. Sketch the different forms of insanity. How is mania to be distinguished from febrile delirium, or from delirium tremens?

4. Describe the general and local symptoms of empyema, its diagnosis, terminations, and treatment.

5. Give an outline of the pathology and treatment of scarlatinal dropsy.

6. Describe the causes, diagnostic symptoms, and treatment of hydro-pericardium. Explain also how secondary effusions into the pericardium may take place.

Wednesday, November 6.—Morning, 10 to 1.

Midwifery.

Examiner, Dr. RIGBY.

1. Enumerate the symptoms of pregnancy; and then state which are the certain and which the uncertain ones.

2. Describe the last stage of natural labour, and your management of it.

3. Enumerate the indications for using, and the rules for applying the forceps:

4. Describe the various forms of contracted pelvis:

M.B. PASS EXAMINATION.—1850.

Afternoon, 3 to 6.

Forensic Medicine.

Examiners, Prof. BRANDE, Dr. PERRY, and Dr. RIGBY.

1. Describe the distinctive characters of oxalic acid, and the means of detecting it, whether free or combined, in organic mixtures.

2. How may the presence of chloroform be ascertained in the blood and in the organised tissues?

3. Describe the symptoms and treatment of poisoning by the essential oil of bitter almonds.

4. A pregnant female is suspected to have died from the effects of saving. On post-mortem examination a green powder is found in the stomach. By what characters would you recognise it to be saving?

5. Enumerate the evidences of recent parturition in a living woman.

6. Describe the condition of the uterus after labour at the full term of pregnancy.

SOCIETY OF APOTHECARIES OF LONDON.

QUESTIONS IN THE EXAMINATION FOR PRIZES GIVEN BY THE SOCIETY OF APOTHECARIES OF LONDON FOR THE GREATEST PROFICIENCY IN THE MATERIA MEDICA AND THERAPEUTICS.

October 1850.

1. STATE the process, and the theory of the changes taking place during the process, of the preparation of *Potasse Antimonio-Tartar.*

2. What are the diseases, and what are the doses, and the most beneficial forms of combination, in which this medicine may be administered? State, also, the doses and states of combination with strict reference to those diseases respectively, and to their stages and complications.

3. Enumerate the preparations of opium, and state the quantity of opium each contains.

4. Describe the preparation, and state the theory of the process in the preparation, of *Potassii Iodidum.*

5. What are the doses, the uses, and the physiological action of this medicine? State, also, the diseases in which the Potassii Iodidum is indicated, and the modes of exhibiting and of combining it for those diseases respectively.

6. Give a general view of the modes of operation, or physiological effects, of medicines.

7. Give a physiological classification of medicines.

8. Enumerate the sub-divisions of the class *Evacuants*, and state the several modes in which the sub-class *Diuretics* produce their effects.

9. What are the modes in which the sub-class *Expectorants* produce their effects?

JAMES CORLEND, M.D., F.R.S., &c.

First-prize, gold medal; awarded to Mr. F. W. Headland, King's College. Second prize, silver medal, awarded to Mr. D. T. Morris, Charing Cross Hospital.

BOTANY.

Examination paper, Wednesday, August 14th, 1850. Hours from 10 A.M. until 6 P.M.

1. "Singula, quæ Creator Ter Opt. Max. in globo terraqueo nostro produxit ordine et nexu inter se coherent mirabili, et a mutuis officiis conservacionem expectant perpetuam."—*Lin.*

Illustrate the above passage, by pointing out the connexions and dependencies of the Vegetable Kingdom.

2. What are the objects proposed by a natural method?

3. Why is the natural method to a great degree artificial?

4. Describe the structure of the anther in Lauraceæ, Berberaceæ, Ericaceæ, and Epacridaceæ.

5. Describe the structure of the gynoecium of gymnospermous plants.

6. What is our present state of knowledge respecting the fructification and germination of Ferns?

7. Describe the development of the ovary, the embryo, and the anomalous corollas of Ranunculaceæ.

8. "Urit amor plantas."—*Lin.*

How far is this true respecting the fecundation of plants?

9. Describe the structure, &c., of the stem and leaves in the specimens numbered 1 to 10.

10. Show the importance of the characters derived from the stem and leaves in the formation of natural orders.

11. Describe the specimens of fructification numbered 1 to 8.

12. Give the reasons for, and against, the admission of Rhizogens and Dictyogens as distinct Classes in the Vegetable Kingdom.

13. Give the character or characters which distinguish the following natural orders from each other, viz. —

Ranunculaceæ	from Magnoliaceæ
Nelumbiaceæ	" Nymphæaceæ
Gnaphalaceæ	" Compositaceæ
Malvaceæ	" Geraniaceæ
Xanthoxylaceæ	" Anacardiaceæ

Rosaceæ	from Myrtaceæ
Umbelliferae	" Araliaceæ
Lobeliaceæ	" Campanulaceæ
Verbenaceæ	" Labiatae
Apocynaceæ	" Asclepiadaceæ
Lauraceæ	" Thymelaceæ
Myricaceæ	" Betulaceæ
Zingiberaceæ	" Cannaceæ

14. Enumerate the principal medical products of the above orders.

N. B. WARD.

There are three Prizes given by the Society—1st. A gold medal; 2nd. A silver medal, and books on Botanical Science; and, 3rd. Books only.

The successful competitors are—first Prize, Mr. Frederick William Headland, King's College; second, Mr. George D. Brown, St. Thomas's Hospital; third, Mr. John Z. Lawrence, University College.

REAPPEARANCE OF THE CHOLERA AT ALGIERS.

WE regret to find, by letters lately received from Algiers, that the cholera has fallen like a thunderbolt on that place, and that in two days 150 persons were swept away.

THE PAYMENT OF MEDICAL REFEREES BY INSURANCE OFFICES.

IN reference to our recent remarks on this subject, it is only fair to state that one of the oldest offices in London—namely, the Royal Exchange Office—has set the liberal example of paying medical referees for their certificates. The Royal Exchange Office was founded in 1720, and does a larger business than the Sun, Rock, Eagle, and Atlas. There can be no doubt that it is a good and safe office for selection.

ROYAL COLLEGE OF SURGEONS.

THE following gentlemen having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners on the 1st inst.:—Messrs. George Phillips Bevan, Beaufort, Breconshire—Mark Edwin Bullen Nicholson, Cambridge—Mark Rowland Day, Oxford—John Frank Ross Lang, Newcastle-upon-Tyne—Adam Fletcher, Bury, Lancashire—James Edward Dickenson, Hart Street, Bloomsbury—Francis Robinson, Nova Scotia, North America—Henry Goode Wright, Hereford—Roger Lewis, Narbeth, Pembrokeshire—James McCaskey, Romford, Essex—and George Hugh Sidley, B.N. This gentleman passed as naval assistant February 7, 1845. At the same meeting of the Court, Mr. James Smith Ayerst passed his examination for naval surgeon. This gentleman had previously been admitted a member of the College; his diploma bearing date April 12, 1847.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 31st October, 1850:—Joseph Brady, Dewsbury—Reuben Sykes, Snaith, Yorkshire.

OBITUARY.

On the 4th inst., Joseph Freeman, Esq., of Spring Gardens, in his 59th year.

On the 5th inst., at 4, Mylne Street, Myddelton Square, John Thorne, Esq., surgeon.

BOOKS & PERIODICALS RECEIVED

DURING THE WEEK.

Principles of Medical Jurisprudence, designed for the Professions of Law and Medicine. By Amos Dean, Counsellor-at-Law, and Professor of Medical Jurisprudence in the Albany Medical College. New York, 1850.

On the Therapeutic Application of Electro-Magnetism in the Treatment of Rheumatic and Paralytic Affections. By R. Froirip, M.D. Berlin. Translated by R. M. Lawrance, M.D. &c.

Deafness practically illustrated. By James Yearley, M.B. &c. 3d edition.

Notice of an Unpublished Manuscript of Harvey. By G. E. Paget, M.D. &c.

The Studies of the Medical Man. By R. Lankester, M.D. F.R.S.

The Races of Man, and their Geographical Distribution. By Chas. Pickering, M.D. With an Analytical Synopsis of the Natural History of Man, by J. C. Hall, M.D. &c.

The Report of the Board of Health on the Supply of Water to the Metropolis. By J. N. Warren, C.E.

The Scottish Temperance Review. Vol. v. No. 2.

The American Quarterly Journal of the Medical Sciences. Philadelphia, October 1850.

The Dublin Quarterly Journal of Medical Science. November 1850.

The London Journal of Medicine. November 1850.

The Pharmaceutical Journal. November 1850.

Casper's Wehenschrift. Nos. 39 to 41, 28th September to 12th October.

BIRTHS & DEATHS IN THE METROPOLIS

During the Week ending Saturday, Nov. 2.

BIRTHS.		DEATHS.	
Males....	770	Males....	404
Females..	749	Females..	481
1519		945	

CAUSES OF DEATH.

ALL CAUSES	945
SPECIFIED CAUSES	930
1. Zymotic (or Epidemic, Endemic, Contagious) Diseases....	312
Sporadic Diseases, viz.—	
1. Dropsy, Cancer, &c.	41
2. Brain, Spinal Marrow, Nerves, and Senses	116
4. Heart and Bloodvessels	51
5. Lungs and organs of Respiration	138
6. Stomach, Liver, &c.	49
7. Diseases of the Kidneys, &c.	8
8. Childbirth, Diseases of Uterus, &c.	6
9. Rheumatism, Diseases of Bones, Joints, &c.	7
10. Skin	3
11. Premature Birth	30
12. Old Age	41
13. Sudden Deaths	10
14. Violence, Privation, Cold, &c.	33

The following is a selection of the numbers of Deaths from the most important special causes:

Small-pox.....	9	Convulsions.....	38
Measles.....	21	Bronchitis.....	59
Scarlatina.....	41	Pneumonia.....	61
Whooping-cough.....	20	Phthisis.....	113
Diarrhoea.....	19	Lungs.....	13
Cholera.....	3	Teething.....	15
Typhus.....	65	Stomach.....	2
Dropsy.....	11	Liver.....	12
Hydrocephalus.....	23	Childbirth.....	3
Apoplexy.....	17	Uterus.....	2
Paralysis.....	20		

REMARKS.—The total number of deaths was 14 below the average mortality of the 44th week of ten previous years.

METEOROLOGICAL SUMMARY.

Mean Height of the Barometer	29.63
" " " Thermometer	46.3
Self-registering do. Max. 63° Min. 23°	
* From 12 observations daily. * Sun.	

RAIN, in inches, '01.—Sum of the daily observations taken at 9 o'clock.

METEOROLOGICAL.—The mean temperature of the week was 3.4 above the mean of the month.

NOTICES TO CORRESPONDENTS.

Mr. F. H. Hewitt.—A letter will be sent in reply to the enclosures received.

The Bed-side Sketches from the pen of Dr. J. C. Hall, of Sheffield, have been for the present postponed. Dr. H. has promised us that they will be resumed in the next volume.

We are compelled to postpone until next week the lecture of Dr. Bellingham, and the papers of Mr. France, Mr. Crompton, Mr. Hunter, and Dr. Snow.

Mr. H. Smith's address is also unavoidably postponed. It will be published in the following number.

RECEIVED.—Mr. W. Parker.—Dr. F. Behrend.

COMMENTARIUM.—In Dr. Jamieson's lecture, last week, page 745, col. 1, line 28, for "pathology," read "psychology."

Lectures.

LECTURES
ON THE
MEDICAL JURISPRUDENCE OF
INSANITY.

*Delivered in the Medical School of King's
College, Aberdeen.*

BY ROBERT JAMIESON, M.D.
Lecturer on Medical Jurisprudence in the
University.

LECTURE VIII.

Testimonial capacity of Lunatics—Civil responsibility in reference to contracts, marriage, &c.—When does insanity justify coercion?—Cases which do not demand the restraint of an asylum—superintendence always requisite—Lucid intervals—how judged of—Recovery—the marks of recovery—Discharge of Lunatics—liberation and emancipation—Criminal responsibility of the Insane—legal test—consciousness of right and wrong—power of self-control—insufficiency of the legal test—evidence of irresponsibility—how sought to be obtained—Medical opinion—how dealt with in law-courts and by the press—insufficiency of ordinary juries to determine upon insanity—necessity for an improved mode of procedure—Punishment of the Insane—mitigated penalties—dispunishable conditions—Does insanity diminish the expectation of life?

Testimonial capacity of Lunatics.—I concluded last lecture with some remarks on the testamentary capacity of the insane, and shall now allude to their testimonial capacity. Those who labour under amentia, mania, or dementia, are unfit to give evidence as witnesses, but the evidence of those labouring under partial insanity may sometimes be admissible. The testimony of a lunatic during a lucid interval in his disease, is received in reference to matters which have occurred during the existent intermission, and which he may be supposed fully to comprehend; but should a paroxysm have intervened betwixt the events and the time that the testimony is required, then his evidence will be held as of little or no value, because it is presumed that the mental attack may have dissipated or distorted his recollection. The testimony of a monomaniac about matters unconnected with his lunacy may be good, but so liable are the emotional faculties to be perverted

in such patients, and so difficult is it to be satisfied of the non-influence of the governing delusion, which may act in the most unsuspected ways, that the testimony, if uncorroborated, is of small value, and even though it stand the tests of recapitulation and cross-examination, should be admitted *cum nota* and with much caution. These are delusions which would incapacitate the witnessing of those possessed by them on any subject. I have more than once known one puzzled to determine without investigation whether the insane statement of an asylum patient were truth, mischievous falsehood, or pure lunacy; so unexpected, yet so plausible, circumstantial, and consistent, has the story been. The testimony of an individual who has truly recovered from insanity, regarding the circumstances of his illness or the events which preceded it, I believe to be very much more trustworthy than the evidence of a lunatic during a lucid interval, regarding even the circumstances occurring during that interval.

Civil responsibility of the insane in reference to contracts, marriage, &c.—Civil contracts entered into by those labouring under general insanity would be void, but in cases of partial insanity a legal agreement is not of necessity void if it be not the consequence of disordered mind, but fair and rational in its character, and accepted or proposed by one ignorant and unsuspecting of the existence of the insanity.

A marriage contracted in a state of general insanity would be illegal and void, as those afflicted by such a state are incapable of a lawful consent. In regard to marriages contracted by those partially insane, there is not an absolute rule. If the marriage were in any way a manifestation of insanity, as the result of insane delusion, or were contracted during a lucid interval by an interdicted lunatic, or were brought about by the collusion of interested parties, the insanity being on the one hand fraudulently taken advantage of, or on the other unsuspected or misrepresented, the agreement might be annulled at the suit of the party injured or misled. Very mad people do sometimes get wed. I have known an instance in which a female was married when in a state of absolute mania. She was under treatment and difficult to control beforehand, and much excited at the time of the ceremony, but next day she was perfectly ungovernable, and had to be sent to a lunatic asylum. Being in different circumstances her maintenance had to fall on the parish, but whether on her husband's or her own became an interesting question. The business went forward in spite of the representations of her medical attendant; the relatives insisting that she was merely what is some-

times called hereabouts "carried," and would get sobered down by being married; the bridegroom that she was crossed and irritated by her friends, and would become quiet and tractable when removed to her new home. You will find it stated, that the behaviour of the person at the time of the ceremony will form evidence of the mental condition and of the validity of the marriage; but in Scotland, where the ritual part of the affair is, as concerns the parties joined, a much more passive matter than it is in England, briefly and privately performed in the bride's house, there is not the same opportunity for extravagance to be manifested; and in this particular case the clergyman, who was unwitting of the true state of matters, although things looked something queer, saw nothing in them, as he thought, for the short time he was occupied, but what perhaps he had seen on other such occasions—the effects of a rather premature and incautious indulgence in good cheer.

When does insanity justify the coercion of the patient?—In what cases are we justified in certifying that an insane person's condition is such as to require his confinement in a lunatic asylum? It has been said that no lunatic should be placed under restraint who is neither dangerous to himself nor to others; but both medical and legal practice will authorise more than this. A lunatic may be lawfully restrained for his own or others' protection, for the control of his conduct, for the requisite care of his person, and for the treatment of his disease. You will be justified in certifying that a lunatic is a fit subject for confinement in an asylum upon any of the following grounds, if these cannot be efficiently dealt with by any other course: viz.—

- To protect him from external danger.
- To keep him from injuring himself.
- To prevent him injuring others.
- To prevent him from injuring property.
- To obviate a propensity to criminal, indecent, and riotous conduct.
- To guard him from maltreatment and neglect.
- To subject him to efficient treatment for the cure of his disease.
- To subject him to efficient treatment for the alleviation of its symptoms, when the disease is incurable.

Before adhibiting your name to "soul and conscience" documents, testifying confinement to be required, be sure that you recognise the existence of some of these foregoing grounds, in combination of course with the fact that the patient is truly insane. Imbecility of mind, or delusion, does not of itself justify restraint; it is the medical necessity of the case, or the

loss of control in the patient, which does so; and even these in special cases may be dealt with otherwise than by confinement in an asylum. In addition to the medico-legal question of restraint, there is a medico-ethical one in regard to its mode. If an insane person be quiet in his conduct, easily directed and superintended, labouring under an incurable form of the malady, and in such circumstances as to be able to afford all necessary expense for comfort and attendance, a medical man should be shy of becoming a party to the confinement of such an individual to an asylum. The good of the patient is the object to be kept in view. Station in life makes an important practical difference in the matter. A poor man when he becomes insane becomes a burden upon others for his maintenance, and however quiet, harmless, and incurable he may be, it is necessary for his due protection and comfort that he should become the inmate of a public hospital. Cases of senile dementia in the better ranks of life do not require confinement. In cases of puerperal insanity also, a lunacy certificate should be a matter of serious consideration, as this form of disordered mind is most frequently curable, and that within a short period. In the better ranks insanity arising from such a cause is more likely to be speedily removed by judicious medical treatment at home or in a private family than in an asylum, and the patient will after recovery be in every case found to be highly pleased that the one course was adopted in preference to the other. I might go on to cite many examples in proof that it is not always either good judgment or fair play to consign a lunatic to the safe keeping of the walls of a lunatic asylum, though it must be admitted to be in most instances, and on the patient's own account, a right, a politic, and an unavoidable measure.

Although restraint in an asylum is not to be accounted necessary in every case of insanity, superintendence and control is requisite in all. Every one who is lunatic ought to be reported to and known by the authorities, if not under confinement; and no one labouring under insanity ought to be permitted to wander about at large by himself, for it is impossible to predict the actions to which he may be impelled in consequence of his mental disease. Although we may be supposed to have sufficient knowledge of the features of his case to measure the extent of his understanding and his amount of self-control, and imagine ourselves able to enumerate all his delusions; yet we cannot foretell or reckon upon the morbid actions to which he may be suddenly led, by insane ratiocination or diseased impulse.

Lucid intervals.—What constitutes a

lucid interval? During what is termed a lucid interval, the lunatic is held to resume the civil position of a sane person, and may enter into an agreement, give evidence, make a will, &c. He is also presumed to be again responsible for his actions. A lucid interval is an intermission of the disease for a longer or shorter period, and is not a necessary, neither a common occurrence, even in acute cases. Such intermissions are never observed in amentia, imbecility, or chronic dementia,—are very rare in monomania, and occur most ordinarily in cases of maniacal excitement. They have to be distinguished from remissions. Remissions have that frequency amongst the insane, which legal writers falsely assume for lucid intervals; wherever there exists any degree of excitement or depression, there are remissions. They are observable, therefore, in the great majority of lunatics—in indeed in every case of insanity, whether chronic or recent, which does not simply consist of congenital mental deficiency: remissions are very common, lucid intervals rather rare. In judging of a lucid interval, the best course to pursue will be to get the patient to exhibit his powers of mind in writing, and then to have a personal interview, in which the history and features of his own case should form the chief matter of conversation. If the personal examination be satisfactory, and also the character of the epistles, and if you find that his feelings and emotions are no longer morbid, but natural, you may safely certify that you consider the condition to be at least a lucid interval, but I would advise you in no case to do so solely upon the grounds of apparent intellectual sanity—the mere absence of incoherence and delusions. A first lucid interval is not to be distinguished from a recovery by its features, but may frequently be suspected from the suddenness of the improvement. The shorter the interval which marks the particular case, the less are you to depend upon the integrity of the mind during the state of calm. The truest lucid intervals most usually occur about regular periods, and last for several weeks or months; they are generally of longer duration than the paroxysms, but as the disease progresses they come at longer intervals and less regularly, they have a shorter duration and are less perfect, having more the character of remission than intermission. The first fully developed intermission is the interval which is most lucid. There is occasionally a very short lucid interval preceding death, which I have not myself witnessed but in some instances of recent acute mania, in which the excitement was so violent as to prove speedily fatal by the exhaustion of nervous energy. The patient, after suffer-

ing for two or three weeks from a state of sleepless, unceasing, and extreme frenzy falls into a typhoid-like condition, manifests a return of soundness of mind, and shortly expires.

In regard to lucid intervals the law exercises a praiseworthy caution. The evidence of sanity must be as clear as were the proofs of disease. Though the validity of a will executed in such a condition has been frequently upheld in law courts, there is no example of any one having as yet been punished for a crime committed in such an equivocal state of soundness, as an intermission of insanity must be considered to be. In all lucid intervals which are not actual recoveries, it is to be presumed that though the symptoms of the malady are for the time inappreciable, pathological causes of the disease still remain. The flame has gone out, but the inflammability continues, and the slightest cause may be sufficient to evoke the fire again before it would of itself burst forth. "Burdened as the criminal law is," says Dr. Ray, "with false principles on the subject of insanity, the time has gone by when juries will return a verdict of guilty against one who is admitted to have been insane within a short period of time before the criminal act with which he is charged."

Recovery.—When is a person to be held as having recovered from an attack of insanity? The following are the grounds which will justify this conclusion.

First, The return of the natural complexion and expression of countenance, and the disappearance of the signs of related physical disorder.

Secondly, The absence of intellectual disorder,—delusion and incoherence; the patient being capable of recognising his insanity, and conscious of its removal.

Thirdly, The absence of excitement, manifested in the return of adequate self-control.

Lastly, The restoration of the emotional faculties to their natural character, the return of the benevolent emotions, the feeling of sympathy for others, the love of kindred, &c.

Such changes in the patient indicate the removal of the pathological causes of the disease, the re-establishment of the understanding, and the restoration of his moral faculties to their healthy tone. When they all concur, you may be satisfied that the patient has recovered from the attack of insanity, but if any one of them be wanting, you must consider that an essential step still remains to be made. It very seldom happens that a patient recovers in one or two of these points without recovering in them all, but it does so happen occasionally, and gives rise to no little difficulty in

determining upon the continuation of restraint.

When once a person has been found lunatic by commission, or his insanity declared in any other published form, the law is very jealous of allowing him to resume his civil freedom, and requires the clearest substantiation of the fact of recovery, before the commission is superseded and free enlargement allowed. To certify a lunatic's recovery you ought to make as scrupulous and careful an examination as you have been instructed to do before becoming concerned in a certificate of lunacy. Be careful not to mistake partial for complete recovery, and remission or intermission of the disease for absolute removal. Unless the patient has recovered in every particular above mentioned, you may be certain that he will not remain stationary after his enlargement, a man with a new personality; and in the generality of instances the chances of relapse are much beyond those of confirmation. As a general rule, you may be doubtful of the stability of recovery directly as its suddenness. If the disease has come on gradually, be sure that it will be still more gradual in its retiring. Every cure has to be tried by the test of time, and should the disorder have manifested the recurrent type, the proof must be a slow one in order to distinguish between lucid intermission and recovery. The distinction of cure and intermission is however more medical than medico-legal, but it is one of importance in reference to the full emancipation of the patient.

Discharge.—When should a lunatic be removable from confinement? It is to be wished that the law with us in Scotland were somewhat explicit on this subject. In the present state of matters, any insane person who is confined in an asylum may be removed at any time by those who have obtained his confinement; the consequence of which is, that many who are progressing favourably enough may be made, through the mistaken conduct of friends often not strong in judgment themselves, hopelessly incurable, and not a few come to perpetrate criminal atrocities. No lunatic should be consigned to an asylum who does not need to be so, but having required this, for any of the reasons previously alluded to, his enlargement should be obtainable only by petition and warrant on sufficient grounds, in the same way as his constraint was effected. In addition to the plea of recovery a patient might be removable for better treatment elsewhere, or be discharged because he is incurable and harmless, or in a lucid interval which former experience has shown may be longer than his paroxysm, but in no case, unless in that of thorough recovery, ought discharge from confinement

to imply full emancipation from control. Even in some cases of recovery it would be well if perfect freedom were to be interdicted, as, for example, when insanity has resulted and recurred from drunkenness, for in every such case, without careful superintendence, discharge is certain relapse, and freedom a foolish and a cruel gift, precipitating its unfortunate possessor, with every exercise of it, deeper and deeper into the darkest gulph of madness. There should also be a control exercisable by competent authority over the managers of public asylums, to prevent them also from dismissing lunatics, unless upon grounds that are satisfactory to those who have entrusted them to their care, and to the sheriff on whose warrant they accepted the trust.

Criminal responsibility of the Insane.—Theorists have occasionally run mad on the subject of criminal responsibility. Some have held that punishment should in every instance overtake crime by whomsoever committed; others that punishment should follow crime in no case, all crime being a result of faulty or diseased organization. Dr. Heinroth of Leipsic's insanity was, that all disease depends on sin, therefore instead of being a plea for exemption from punishment, is but the more a proof of guilt.

An English judge tells us, that medical men have the delusion that insanity renders a man dispensable, which is a delusion of the bench; such a mistake is not to be found recorded by any English medical authority. The insane we all know may be legally punished, whether justly or not. There is an insanity which annuls criminal responsibility, and an unsoundness which leaves it unmitigated. How are these distinguished? The law directs the application of the following test:—Was the individual's disease of the mind such as to make him incapable of distinguishing right from wrong at the time he committed the offence? if so, he has a criminal capacity; and if otherwise, he is not guilty on the ground of insanity. The phrase "right and wrong," may be read lawful and unlawful, legal and illegal, and the person be supposed irresponsible, either on the ground of perverted moral sense, thinking wrong right, or of obscured intellect, being incapable of remembering and reflecting, and having no right consciousness of the relations of things. How is this knowledge of the criminal's mind to be got? It is sought for by an investigation of the history of the offender previous and subsequent to the act, in order to discover the character of his immediately antecedent or subsequent conduct. The fore or after existence of diseased mind, and the value of the indications of it, are referred to medical opinion.

The deduction as to the consciousness or unconsciousness of right and wrong in regard to the act itself, is left to the jury.

Now let us consider this test, and the way it is managed. The test is sufficient in cases of amentia, mania, and dementia, the patients in such forms of insanity manifesting in their general conduct evidences of non-development or disease, and clear incapacity for competent ethical or metaphysical distinctions, but is I believe incapable of application or insufficient in cases of partial insanity, the sole cases in which difficulties occur, and special tests are desirable. On the one hand, we may suppose an individual unconscious of right and wrong, and yet not the subject of disease, the voice of conscience being silenced by vice, or perverted in its sound by false training, false reasoning, false principles; on the other hand, and here we do not presume, but assert, a person may be conscious of right and wrong, and yet not be a proper subject of punishment. Before a person can be deemed responsible for his actions, he must not merely have the power of *distinguishing* right from wrong, but the power of *choosing* right from wrong; a criminal being properly punishable, not because he knew good from evil, but because he voluntarily did the evil, having the power to choose the good. If a special test of insanity were to be insisted upon, the power of self-control, as being the true index of responsibility, would seem to be better than that of the integrity either of consciousness or conscience. Had the lunatic, at the time of committing the deed, a knowledge that it was a criminal one, and such a control over his actions as might, if exerted, have hindered him from committing it? Most lunatics have an abstract knowledge that right is right, and wrong, wrong;—as much of it as should keep them from being guilty of unlawful deeds, were but such knowledge sufficient for that end,—but the voluntary power over actions and thought is in every case impaired. I do not say that free agency is annihilated; this were untrue; there could then be no moral treatment of insanity; but it is much limited, and overruled by various insane motives. Lunatics have that amount of freedom of will, which it is philosophical, charitable, and advantageous to recognise for their benefit, but at the same time such a defect of free agency as makes the full burden of responsibility to imperfect human legislation, a discreditable and unjust oppression. Many of them may be fully accountable *ex foro conscientie*, but in all other courts, if the insanity be apparent, the defect of self-control should be presumed to exist, and the individual condemned to restraint, or, if considered liable to punishment, subjected

to only a mitigated penalty. There are many states of insanity in which the will is not completely fettered. When the disease is commencing, the will may often be observed struggling before it is overcome; indeed, a highly energetic will may prevent insanity, it may uproot or control a delusion. When the disease is retiring, the will may also be observed gradually re-asserting its authority over the morbid fancies. Here is an example. A recovered patient, to whose narrative I have more than once referred, was directed in his illness by voices which he heard misleading him. They told him that he was in heaven, and he believed them; that such and such an individual was the Son of God, and the person became to his belief the Divinity; but by and by we find that the voices talked to him in a very singular strain; they said, "You are in a lunatic asylum, *if you will*; if not you are in such and such a place."—"That person is Samuel Hobbs, your attendant, *if you will*; if not he is the Saviour." In short, he was beginning to recover from his delusions, or rather from the manifestations of them; his madness was becoming a matter of his own choice; his will was becoming free, and the state of responsibility returning.

In order to uphold the inference of the unconsciousness of right and wrong, when the plea of insanity is urged, evidence is sought of the existence of a sufficient degree of delirium, delusion, or imbecility of mind, either antecedent or subsequent to the action. No direct conclusion on the point is allowable from the character of the act itself, and on this account it may happen that the best evidence of insanity is rejected: indeed, cases of undoubted insanity from time to time occur, in which there is no sufficient evidence of the morbid condition, apart from the circumstances of the criminal act for which the person is tried; and it sometimes will happen also that these are so extraordinary in their kind, as to compel a verdict of insanity, despite legal orthodoxy. The important point of hereditary predisposition has been objected to as part of the evidence in defence, but I conceive that the danger to be dreaded from allowing such a circumstance its due force, is quite counterbalanced by the chance of injustice which may result from its rejection. Delusion is no adequate plea in any case where it cannot be shown to have impelled the criminal to his crime: in this rule, if absolute, there is manifested the little knowledge that may lead to much error. An insane act is the index in most cases of a delusion, yet the motive may not be apparent though the result is, and the delusion which seems merely to be co-existent with—not related to the act—may yet be

impulsive; for the connection between an act and a delusion is often of a most insane kind, not to be surmised, nor understood when known, but existing nevertheless. Even when the crime is shown to be a morbid result, it may not be a legally sufficient plea for exculpation; for, on the "right and wrong" principle, it matters not that the act flowed from a delusion, if the person was at the time aware of its illegality and its consequences.

The medical witness is not much to be envied when summoned for the defence in cases where the plea of insanity is raised, for though his opinion on the existence of insanity be worth that of jury and judge together, it may be suppressed by the bench, in some manner not very complimentary, and ignorantly assailed in the criticisms of the press. I declare it to be impossible for any one to tell you with certainty what is allowable medical evidence in such cases. Do such and such facts in the evidence, or such and such facts in the case, indicate insanity? Was the prisoner insane at the time that the act was committed? Was he labouring under delirium or delusion? Could the crime have flowed from his insane notions? These are all questions which the judge would probably object to, or find fault with being answered if they were put, as they have been, by counsel. The ordinary objection is, that to question the medical man so, is to make a jurymen of the witness; this does not seem a sufficient reason, for the opinion conveyed in the answer, though a scientific opinion, is not a verdict or declaration, unless the jury see fit to adopt it. Scarcely an instance occurs of acquittal on the ground of insanity, in a case of much public interest, that the medical evidence is not impugned by smart editors, in astonishing leaders on the incompetency of medical knowledge in such matters, and the punishable capacity of the insane. The proceedings and decisions in our courts in cases of diseased mind are discreditable to the judiciary of the age; the dogmas of the law stand in much need of being reconsidered, and the whole course of procedure amended. It is by the influence of medical, and not of legal expositions, that the desired reforms are likely to be brought about. "The same courage," says Dr. Conolly, "which causes the physician to brave the dangers of pestilence, should support him in this duty, beneath the assault of pestilent tongues and pens. Not the voice of the people calling for executions; not the severities of the bench, throwing down pathological truth, should shake his purpose as an inquirer and a witness. His business is to declare the truth. Society must deal with the truth as it pleases."

The jury determine on the guilt of the

offender, which they are understood to do by solving the question of consciousness of right and wrong. To do this, they are not of necessity permitted the light of a scientific opinion on the point. Without adequate knowledge of the phenomena of diseased mind, and unguided by those who are familiar therewith, it is not to be wondered at that great mistakes are made, that verdicts are inconsistent with the evidence brought forward, and that parallel cases are decided in opposite ways. It would be better that the ordinary assize determined on the mere fact of the commission of the crime by the accused,—on the guilt of the person apart from the insanity,—and that the responsibility of the offender should be a matter for the after consideration of a special jury. When a presumed lunatic commits an offence, let him be tried first on the charge, and be entitled, on the certificate of his mental state by competent examiners, to appeal against sentence, on the ground of insanity; then let his mental condition be testified to, and proved before a jury, specially qualified to understand and appreciate the evidence. Such a jury might, as suggested by a writer in the *Journal of Psychological Medicine*, consist in England, of the Lunacy Commissioners, and of medical men experienced in mental disorders. The matter to be investigated should be the diseased or defective condition of the offender, and whether it be such as to limit or annul his responsibility. The evidence should be obtainable from the history previous to the crime, the circumstances of the deed itself, the history subsequent to the crime, and the personal examination of the prisoner.

A lunatic who is found guilty of a capital charge, ought to be, and generally is, confined for life in a lunatic asylum. When the crime is of less magnitude, the confinement should be until recovery, and for a certain length of time beyond it, in order to prove the stability of the cure; before enlargement the patient should be certified to be sane in mind by competent examiners, and the evidence of recovery tested by a special jury. Some have advocated the punishment of all partial lunatics who commit offences against the law, on the principle, not merely of example to all, but also on that of deterring more particularly those who are disordered in mind from giving way to criminal impulses. For the former object we have unfortunately opportunities sufficient, without dealing by disease as if it were a crime, and the latter is not capable of being affected by such irrational means. Oh! but punishment is found to have its advantage in hospitals, as part of what is called the moral treatment of the insane. It may be so, perhaps, but

then it is punishment of a beneficial kind, applied to the lunatic himself, and not inflicted on his fellows for his warning and improvement. No lunatic will be edified and improved by the punishment of an insane offender, for he will not consider himself as in the class for whom the experiment is specially intended. If capable of being deterred, the example of the penalty endured by those who are truly criminal will amply suffice for the purpose. An insane criminal action is committed either in delirium—the patient not knowing what he is about; in delusion—the offender believing the act to be not criminal and avoidable, but necessary and right; or in obedience to diseased impulse, when to choose and to do otherwise is impossible. Under peculiar circumstances, a lesser than the ordinary penalty might be inflicted on the partially insane, just as we see occasionally ordered by magistrates for children under the age of full responsibility; but in general, I believe the punishment of lunatics to be useless for any good purpose,—a mistake and a folly, if not even a sin.

To conclude. As a general rule a lunatic is properly punishable, because disease has restricted or destroyed his capacity as a free agent. Every lunatic should be under control, to prevent him from illegal actions. No one labouring under amnesia, or mania, is a fit object of punishment. A monomaniac ought not to be punished, when it is found that the crime has flowed out of the governing delusion; when the connection betwixt the two cannot be traced, if punishment is awarded, the penalty should be a mitigated one. The morally insane should not be punishable to the extreme. No one labouring under secondary dementia ought to be accounted punishable; and in no case of imbecility, in any degree, should punishment be to the extreme.

Does Insanity diminish the chances of life?—Lunatics are more liable than others to the whole class of nervous disorders, and especially to epilepsy, apoplexy, and paralysis. The peculiar condition of a lunatic's nervous system renders other disorders, with which he may become casually affected, more liable to have a fatal termination. I must tell you, however, that some have held an opposite opinion. It has been asserted that insanity does not reduce the chance of life below the averages. Independent of its complications, there are many grounds for considering that insanity is a condition unfavourable to longevity; instead of enlarging on these, however, I shall rather lay a proof of the proposition before you. The average age at death, in the York Retreat, was under 43 years; the average age at which the

disorder was manifested, was 38. Now, says Mr. Thurnam, the able statistician of that hospital, the expectation of life at 38 years of age, according to the most recent researches, is not less than 28 years, so that the mean age attained should have been 66, instead of 48. The average age at which lunacy appears is 38, at which age the expectation of life is 28 years more; but the average age of lunatics at death is 48,—only 10 years more—instead of 66; hence, insanity shortens life. In 126 fatal cases of insanity in the Aberdeen Asylum, the average is, I find, 46 years nearly. The statistical tables of the York Retreat lead to another conclusion, less expected, which also shows the unfavourable influence of the disease on the chances of life. It is this: the duration of life is not of much higher value even in those who recover, for the average age at death in those who had been discharged recovered was 57, instead of 66, or nine years less than the average probability. The subject is of much importance in connection with life-assurance.

TESTIMONIAL TO DR. CANHAM, OF RAMSGATE.

At a public meeting recently held at the Town Hall, Ramsgate, it was proposed by Mr. Whitehead, seconded by the Rev. G. W. Sicklemore, and unanimously resolved:

"That this meeting having learned, with much regret, the intended departure of Dr. Canham from Ramsgate, are anxious to mark the grateful sense they entertain of his public services, and their sincere esteem for his private worth."

Proposed by Mr. Sackett, seconded by Captain Hitchens, R.N., and resolved unanimously:—

"That a piece of plate be presented to Dr. Canham, as a testimonial, with an inscription embodying the sentiments expressed at this meeting."

Proposed by the Hon. H. S. Law, seconded by Lieut. Hutchinson, R.N., and resolved unanimously:—

"That a subscription be entered into for this purpose; and that a committee be formed to carry out the intentions of this meeting."

* * * We perceive, by the list of subscriptions, that the sum of £2183. 9s. has been already contributed. This is a satisfactory proof of the high estimation in which Dr. Canham's professional services and private worth are held by the inhabitants of Ramsgate.

Original Communications.

CASES AND OBSERVATIONS IN SURGICAL PRACTICE.

By DICKINSON W. CROMPTON, F.R.C.S.

HYDATIDS IN BONE.—UNUNITED FRACTURES.

I HAVE the authority of Dupuytren for stating "that the presence of hydatids in the substance of the humerus is a very unusual circumstance: indeed, the cases cited by authors of hydatids in the bones generally are very few, and their diagnosis extremely difficult, not to say impossible." In Le Gros Clark's edition of Dupuytren's Clinical Lectures, one case is recorded of such disease which ended in death (p. 34), to which I beg to refer, as there is a striking similarity in the course of the case to the one I wish to report, except that the Frenchman died under the exhaustion of profuse suppuration, and gave an opportunity for a post-mortem examination; whilst my patient, I am happy to say, after much difficulty, is now in health, with a very useful, if not perfect, arm: I believe by this time she is completely recovered. There are few cases of hydatids in bone recorded, though Professor Miller (p. 489 of his 2d edition of Principles of Surgery) says—"Hydatids have not unfrequently been found in the cancellous tissue of bone." On referring to the cases, I find them alluded to by different authors; but the references are, for the most part, to the same cases. Mr. Stanley refers to a few cases only: and the one seen by him in St. Bartholomew's Hospital proved fatal, after severe constitutional disturbance from suppuration. A case recorded by Mr. Keate (Med.-Chir. Trans. vol. v.), where the disease was in the bones of the cranium, ended in restoration to health. Two others, in which the disease occupied the tibia (one recorded by M. Corvisart, Journ. d. M.-d. Chir., treated by M. Cullerier; and the other by Mr. Wickham, in the Lond. Med. and Phys. Journ. vol. lvii.), are also to be placed amongst the successful cases; but a third, recorded by Mr. Webster in the New Eng. Journ. of Med., vol. viii. old series, and vol. iii. new series, p. 29, 1819 (which, by the way, was a case that occurred in Guy's Hospital, 1815),

proved fatal, even after amputation had been had recourse to, on account of the great constitutional disturbance that suppuration of the tumor produced. Dupuytren refers to the case of hydatids in the tibia treated by M. Cullerier, recorded by M. Corvisart, before mentioned. He himself once saw hydatids in the body of a vertebra, and once also in the lower jaw.

The disease, at all events, when met with, is one attended, at some period of its course, with considerable danger to the limb, if not to the life of the patient, as the cases above referred to are sufficient to prove.

CASE.—*Ununited Fracture of the Humerus—Hydatid Cyst—Seton—Cure.*

Mary Ladbury, set. 27, a dressmaker, was admitted into the General Hospital, Birmingham, June 4th, 1849. She stated that four months ago she fell down stairs and broke her right arm. She was attended by a surgeon at Redditch, who placed her arm in splints, and, after a time, tried various methods to produce union of the bone, without success. She considers her general health to have been good previous to the accident. The fall was one of great violence. The arm was fractured about the middle, just below the insertion of the deltoid. The point of the fracture was extremely moveable, so that I could easily bend it to a right angle. On the next day the ends of the bone were rubbed together, and the arm secured in splints in the usual manner, only that greater pressure was used with plaster and bandage than would have been justifiable in a recent fracture. The arm at this period was rather thinner than usual, which I attributed to the want of use, and the long employment of splints. There was room between the ends of the bone to press the fingers upon the ligamentous structure that united them.

She was ordered meat daily, and beer.

July 2d.—On examination, no benefit was perceived. The ends of the bone were again well moved upon each other till some pain and heat followed, and a starched bandage was applied from the wrist upwards to the shoulder.

28th.—The bandages were again removed, and no improvement was observed. I therefore, on the 29th, passed a large needle (formed at the end like a spear, and armed with a thick skein of

ligature thread) through the arm between the bones: much force was required to push so large a needle through. I held the integuments and the vessels and nerves tightly inwards, and punctured to the bone with a scalpel, so as to inflict as little pain as possible; and, as the needle emerged through the ligament, and could be felt on the outside of the arm. I cut down upon the point and released it. The arm was supported in a sling, and ordinary splints loosely applied to the humerus.

August 3d.—Considerable inflammation had taken place; the arm was much swollen. *The seton was removed*, and pus of a healthy character discharged. A poultice was applied.

24th.—The inflammation had nearly subsided, but no attempt at union had been made. A starched bandage was again applied from the wrist upwards, leaving openings for the discharge of the matter.

September 6th.—On squeezing the arm, which was swelled and painful, pus was discharged, and at least a teaspoonful of gelatinous matter was passed out of the anterior wound.

10th.—On again squeezing the arm, a few white globular masses were discharged; they were opaque externally, but, on puncturing, were found to contract and spit out a limpid fluid. These I believed to be hydatids that had perished from the presence of pus, which appears to be a fatal poison to them. Some few were whole, but many more were broken, and evidently had been larger cysts than those which escaped unbroken. The suppuration was very abundant and offensive. Gutta percha splints and bandages were now used to prevent motion as much as possible, and to support the arm, which was otherwise very painful to the patient.

26th.—A thickening was evidently taking place, as if from the effusion of lymph under the integument of the whole arm; and mobility of the separated ends was consequently diminished. The wound was looked at and dressed every other day. The matter was allowed to discharge itself into cotton wool, which I always apply under gutta percha splints when a bandage is not used beneath them, as gutta percha is apt to irritate the skin of most patients. Hydatids continued to be discharged on pressure at each dressing, to the number, perhaps, of from six to a dozen.

some skins appeared to have belonged to individuals as large as a small nut, others as large as shot of different sizes.

October 4th.—New bony matter appeared to be forming, particularly from about an inch above the elbow, and passed upwards in a thin crust, so that pressure of the fingers produced a crackling sensation. Hydatids continued to be discharged: and, after careful search, we were able to detect the peculiar hook-like processes, said to be diagnostic of the presence of true hydatids. The microscope had been frequently had recourse to, for the purpose of ascertaining the true nature of the opaque bodies that had escaped from the wounds, by Dr. Heslop, Dr. Bell Fletcher, and myself, and also, on one occasion, by Dr. Gairdner, who was passing through Birmingham: each, with true philosophical caution, hesitated to give a name to these bodies till the presence of the hook-like processes was evident.

10th.—The discharge varies much in quantity; but the arm, even above the shoulder, and above the deltoid muscle, is now much swelled, and feels doughy, as if great suppuration was about to take place. The girl looks pale, is emaciating, and her health is evidently much depressed by the present state of the discharge.

21st.—The arm, up to and under the deltoid, as well as over the acromion, part of the scapula, and under the humeral end of the clavicle, is considerably swollen, red, and in part softened, so that fluctuation is perceptible; on steady pressure over these parts downwards towards the wounds, about six ounces of pus, with a quantity of hydatids, were pressed out. An abscess was opened in the axilla on the 24th.

29th.—The discharge is so great as to require the arm to be dressed every day: two smaller collections of pus have been evacuated, one under the acromion, the other at the back part of the arm; yet the arm is becoming firmer, and the number of hydatids discharged is much diminished. The arm, elbow, and shoulder-joint, are kept as immovable as possible by gutta percha splints and bandages.

November 15th.—The improvement in the arm is steady, but the discharge is still so great that the patient's health suffers very much. I have, therefore, recommended her to go into the country.

28th.—Abscesses still continue to come to the surface, which I open. There is one place in the posterior part of the arm from which I can generally press out matter, and a broken hydatid skin or two through the wound in the anterior surface of the arm.

December.—This patient is now returned home with the arm quite firm, but at present, from the consolidation of the integuments and muscles caused by such extensive suppuration, she has not much power of motion, or of use in the extremity. She still looks pale, but is improving.

June 27th, 1850.—I have seen Mary Ledbury to-day. The use of the arm is much improved; she can sew a little, but cannot quite straighten the elbow, or raise her arm to the horizontal position from the shoulder. There is still some little purulent discharge, and minute exfoliations have taken place.

Hospital practice gives the surgeon frequent opportunities of seeing cases of delayed union. Within the last seven years I have seen three cases of ununited fracture of the humerus, in all of which the seton was tried—in two successfully, after extensive suppuration. In the third I could not pass the needle between the ends of the bone, which was broken obliquely at about the insertion of the deltoid. The man was a very powerful person, and was stronger in that arm than I was with either or both of mine; so I advised him to be content, and let the arm remain as it was.

Three cases of ununited fracture of the tibia have been under my care, and all much benefitted by the use of the seton, pressure, and rest combined. I believe they are all well now, but I have not seen any of them for the last few years. A fourth case was fracture of the tibia, with other injuries, under the care of Mr. Wood: the man had severe pleurisy, during which the fractured extremities became loose. The seton was introduced between the ends, and sufficient action renewed to produce perfect union. I have also seen two cases of ununited fracture of the thigh, one close above the knee-joint. The man could manage to walk pretty well by the aid of a strong leather case. On that account, therefore, as well as because of the close proximity of the fracture to the joint, I recommended nothing more to be done.

These cases led me to endeavour to collect the recorded cases of ununited fractures, with a view to ascertain the bones, and the particular situation in each bone, in which this unfortunate termination had been observed. I had collected 86 cases when M. Malgaigne's extensive work on Fractures and Dislocations came under my notice. Under the head of "Ununited Fractures" I found references to a paper, by Mr. Norris, in the American Journal of Medical Science, vol. xxix. Jan. 1842, Through the kindness of my friend Dr. Edmund Parkes, I obtained the volume, and was surprised to find that so excellent and extensive a statistical work on such a subject had been (as far as I am aware) unnoticed by any writer on this side the water, except M. Malgaigne, who certainly has made full use of it. I cannot but think it would be well worth the attention of some of our journals, and be very desirable (with the consent of the writer) to republish both the paper on Ununited Fractures and the equally valuable and laborious one on Aneurism, for which the profession is so deeply indebted to that gentleman. In the meantime, I append an abstract of the *résumé* with which Mr. Norris concludes his paper on Ununited fractures:—

Of 150 cases of ununited fractures—

48	occurred in the femur.
33	" " leg.
48	" " humerus.
19	" " forearm.
2	" " jaw.

Of 112 cases, in which the age is noted, there were:—

Between 10 years and 20	. . 14
" 20 " 30	. . 53
" 30 " 40	. . 21
Above 40 24

M. Malgaigne has with care made out a list of 104 cases, with the precise date of the fracture as to the age of the patient suffering from the accident, with a view to the theory of the greater difficulty of union in old people. He finds

1	under 5 years.
2	from 5 to 10
3	" 10 to 15
4	" 15 to 20
50	" 20 to 30
19	" 30 to 40
14	" 40 to 50
6	" 50 to 60
3	" 60 to 70
2	above 70

Mr. Norris's summary of treatment is as follows:—Of 46 cases treated by seton, 36 were cured; 3 partially so; 5 received no benefit; 2 died.

Of 38, in which resection, scraping, &c., were used, 24 were cured; 1 partially so; 7 received no benefit; 6 died.

Of 36, in which pressure and rest were used, 29 were cured; 1 partially so; 6 received no benefit.

Of 8, in which caustic was used, 6 were cured; 2 received no benefit.

Of 11, in which frictions were used, 11 were cured; but, in 36 cases cured by seton, friction had failed in 8; and,

in 24 cases cured by resection, friction had failed in 5.

Of 11 cases in which other means were used, 5 were cured by iodine; injection, 1; erysipelas (!) cured 1; and hot iron, 1.

Amputation (!), 5 cases. One was cured; 2 died; 1 failed; 1 not stated.

The table of results from the five methods of treatment most commonly used—namely, 1st. Compression and rest; 2. Friction; 3. Seton; 4. Application of caustic to the seat of fracture; 5. Resection of the ends of the bones—

Shows, that out of 36 cases included in his table treated by compression and rest, 29 were cured Of these—

13 were in the femur, of which 9 were cured.				
7	"	leg	"	7
12	"	humerus	"	9
5	"	forearm	"	4

From the seton and its modifications, in 46 cases

13 were in the femur, of which 9 were cured				
10	"	leg	"	10
16	"	humerus	"	10
6	"	fore-arm	"	6
1	"	jaw	"	1

Accidents following the use of the seton in the 46 cases occurred 12 times—namely, arterial hæmorrhage twice; fever, erysipelas, or profuse suppuration, 10 times.

From the use of resection in 38 cases, 24 were cured; 1 amended; 7 failed; and 6 died. Of these,

12 were in the femur, of which 7 were cured. Rather more than half!				
6	"	leg	"	5
12	"	humerus	"	6
7	"	forearm	"	5
1	"	jaw	"	1

and one amended

In 17 of the cases in which resection was employed, other methods had failed; the seton was used six times.

In the 38 cases in which resection was used, accidents *not* ending in death, but dependent upon the operation, followed 9 times—namely, erysipelas 6; profuse suppuration and abscesses 2; phlegmasia dolens 1.

Mr. Norris concludes that—

1st. Non-union after fracture is most common in the thigh and arm.

2nd. That the mortality after operations for cure follows the same laws as after amputations, and other great operations upon the extremities—viz. that the danger increases with the size of the limb operated upon, and the nearness of the operation to the trunk; the mor-

tality in them being greater in the thigh and humerus than in the leg or forearm.

3d. That the failures after operations for their relief are most frequent in the humerus.

4th. That after operations for the cure of ununited fracture, failures are *not* more frequent in middle-aged and elderly people than in young subjects.

5th. That the seton and its modifications are more safe, more speedy, and more successful, than resection or caustic.

6th. That incising the soft parts previous to passing the seton augments the danger of the method, though failures are fewer after it

7th. That the cure by seton is *not* more certain by allowing it to remain

for a very long period, whilst it exposes to accident.

8th. That it is least successful on the femur and humerus.

Such are some of the important results for which we are indebted to the great industry of Mr. Norris: five times more than is contained in many thick octavos—not to mention the statistical paper on Aneurism which has been inserted in a more recent number in the same unassuming manner. He must be a bold man who, after reading his paper and the case in the "Lancet" of October 19, 1880, would again first break by the force of pullies, then reset, then resect, and then amputate, for a firm though badly united femur.

M. Malgaigne has given a statistical table of the relative frequency of fracture in all the bones of the body; but he has not particularised the exact situation of fracture in each bone. Mr. Adams has given similar tables in some volumes of the MEDICAL GAZETTE.*

Until we have tables that particularise the exact situation of the fracture, we cannot compare the relative frequency of ununited fractures in the various bones with fractures that unite in a normal manner. Such tables could easily be made out by an intelligent house-surgeon of any of our hospitals, who necessarily sees the cases of fracture at the earliest period, and before swelling has occurred, or a right position been given to the bones. I think it very probable that some law would be found to exist that might explain the reason of its occurrence. Possibly it might be found that fracture near to a joint, or to the insertion of some powerful muscle, would have much influence in producing such an accident, on account of the increased difficulty, in such situations, of procuring the required immobility. It is certain that peculiarity of constitution will not account for the production of ununited fracture in a great proportion of the cases in which it has occurred.

Birmingham, Oct. 26, 1880.

* Malgaigne's table of the total number of fractures in 2222 patients is—

Of trunk	379
Superior limbs	925
Inferior limbs	1694

FURTHER REMARKS ON THE EMPLOYMENT OF CHLOROFORM BY THIEVES.

By JOHN SNOW, M.D.

In a former communication on this subject* I said, that if "thieves and prostitutes were to resort to the use of chloroform in the public streets, in the manner alleged, the attempt would only lead to their instant detection on the spot." This opinion has been more than confirmed by what has since occurred. In two or three cases in which it was alleged that robberies had been effected by means of chloroform, that part of the accusation which related to the use of this agent broke down on the cross-examination; whilst in two instances—the only ones, as I believe—in which it has been proved that chloroform was used with felonious intent, the culprit failed to induce insensibility, and was detected on the spot, although the attempt was not made in the street, but in a more secluded place. The first of these cases occurred in London, a few months ago. A young man returning after midnight with his sweetheart from a dance at a public-house, induced her to accompany him down a Mews or stable-yard. He there took out a bottle containing chloroform, and poured some of it on a handkerchief, which he applied to the young woman's face. She tore away the handkerchief, and called out in such a manner as to bring a policeman from a neighbouring street to her assistance, who secured the offender, and picked up the bottle, which the latter had thrown away in his flight. The reader will probably remember that this case was amicably compromised, by the prisoner marrying the complainant, whilst he was remanded, and out on bail.

The other case, which happened recently, and is detailed in the MEDICAL GAZETTE of yesterday, is of a more atrocious kind. A man who was lodging at an hotel in Kendal, secreted himself in the room of an elderly gentleman, whom he attacked in the middle of the night with a rag steeped in chloroform. The means used, so far from keeping the gentleman asleep,

* MED. GAZ. last volume, p. 237.

had a contrary effect; and although the robber struggled with his victim till blood was drawn by his violence, and the bedding had fallen on the floor in the scuffle, he did not succeed in making him insensible, or in preventing his bringing assistance by his cries. It is quite true that the attempt, had insensibility been induced, might have resulted in murder; for the thief in the dark, and without experience to guide him, could not have known when to stop in time to spare life, if that were his intention, I therefore coincide in the remark in the leading article of the *MEDICAL GAZETTE* of yesterday, respecting the insufficiency of eighteen months' imprisonment as a punishment for such a crime.

There may, however, have been circumstances which would have some weight with the Bench, and have not appeared in the newspapers.* I can easily suppose that it was the man's first attempt at robbery; for I cannot imagine that an experienced thief, or one who had the advantage of belonging to a gang, and therefore of consulting about, and trying beforehand, the means to be used, would, on hearsay or newspaper evidence, have adopted the use of an agent so ill suited to assist him. Again, a chief object of punishment is to protect the public by preventing future crime; but in this instance the signal failure of the attempt at robbery will do more to deter others from using a like means than any example that could be made of the criminal. I think that this kind of attempt is not very likely to be repeated; and although chloroform is one of the thousand articles the use of which should be confined to medical men, yet the subject, in my opinion, is hardly of sufficient importance to require legislative interference. The murders by arsenic, in the rural districts, are a disgrace to the age and country in which we live, and have long and loudly called for a legal enactment to limit the sale of this poison: but if Parliament have to discuss what articles have to be admitted into the provisions of a "Sale of Poisons Restriction Bill," I am afraid that we shall be long in obtaining such an enactment; and if, when at last obtained, it be complicated by including too many substances, it will not work well.

The public have been greatly alarmed about the employment of chloroform by thieves, but what they really have to dread is, that robbers will still resort to the old means of the bludgeon, the pistol, and the knife, and not to one which allows the victim so good an opportunity of escape, and themselves so great a chance of detection. Every person who has inhaled chloroform must be quite aware that it could never have been given to him, in his sober senses, without his knowledge, even though every care were used to lessen the impression it makes, by beginning with the vapour largely diluted, and gradually increasing its strength; and no domestic animal, however tame, can be induced to take chloroform voluntarily, but before being made insensible, or in the least affected by it, must always be in some way secured. Therefore, to use chloroform for the purpose of overcoming a person is to adopt a means that cannot be put in force till he is already overcome, and involves a difficulty just like that contained in the juvenile problem of catching a bird by applying a little salt to its tail.

*** Chloroform has been used in France for the perpetration of rape, and the offender tried and convicted. We hope Dr. Snow's prediction, that it cannot be used for robbery without the certainty of failure and detection, may not be proved wrong by experience.

ON CONDUCTORS OF SOUND.

BY JOSEPH SWAN.

IN mammalia the bones of the skull, the external walls of the tympanum and the ossicula, are not so hard as the petrous portion in which the labyrinth of the ear is placed. Sounds cannot extend from the ear except in a slight degree beyond the anterior point of the petrous portion; they are therefore expended on the cells of the mastoid process posteriorly, and on the concha. When the bones of the skeleton are light, as in small animals, the same thickness of the petrous portion does not exist, but the hearing is not then deteriorated, as the parietes of the labyrinth, from their hardness, are still capable of receiving and modifying sounds to a nearly

similar extent. The reception of sounds may then be clear, but there is a deficiency in the sense of solidity and power, so that very loud sounds are tremendous and overwhelming. The petrous portion, by giving a sense of solidity, allows a superior mode of discrimination, and fits the animal for acting steadily, especially in combat amidst conflicting sounds. In birds the freedom of communication between the interior of the bones and the air causes slighter impulses necessary, and, therefore, very slender ossicula. The semicircular canals and cochlea are seen to a great extent from the cavity of the skull, as in the smaller mammalia, and loud sounds therefore terrify them in the same manner. In both mammalia and birds, the bones, from their hardness, would readily conduct sound, but the joints and soft parts, and especially the integuments and their coverings, are unfavourable. When the body is recumbent on hard substances, much of the sound received from them is mechanically conveyed through the bones of the head to the ear.

In amphibia the bones of the skeleton are very hard, and in some instances the skin from its hardness resembles bone; both are therefore capable of conveying strong impulses from the ground.

In cartilaginous fishes the bones are not so hard, but there is a power of continuing similar sounds from the ground, as in amphibia. Osseous fishes probably do not receive such strong impulses from the water alone, as the cartilaginous do from it and the contiguous ground, and therefore are provided with hard stones, which are better conductors of sound. Amphibia and cartilaginous fishes have soft cretaceous matter in the sac of the labyrinth, for lessening and modifying the impulses received from the ground, which would otherwise render nugatory the influence of such sounds as are usually determined by the labyrinth.

In many instances of mammalia and birds in which the petrous portion of the temporal bone does not surmount the semicircular canals, a space is left which is occupied by a lobule of the cerebellum, but this has no communication with the labyrinth. It is probable that the molecular form of the grey

matter prevents impulses from reaching the brain, in the same manner as the molecular form of other matters impedes the progress of sounds to the ear, and, through this, to the nerves and white matter of the brain.

From many experiments it appeared that ashes from a coal fire, coal dust, sand, wheat flour, and powdered chalk, were bad conductors of sound. When each of them—except wheat flour, which was not tried—was mixed with water, the conducting power was somewhat increased. Sound passed readily through oats, also through wheat bran. A piece of chalk, about seven inches square, had a cavity about three inches deep made in it, for holding a watch placed flat; powdered chalk was then put over the watch, so as to fill the hole, and there was a very faint sound heard; but when the powdered chalk was pressed down, the sound was much louder; the sound was also increased when powdered chalk made into a mass like mortar surrounded the watch tied up in oiled silk. The same was done in the other experiments with wet matters, and with dry the watch was enclosed in paper; in some the watch was surrounded by the matters in a porcelain vessel—in the others, in one of glass.

It seems that the more the several substances preserve their molecular form, the worse conductors they are; and, when the molecules are aggregated, there is a difference of this power according to their degree of cohesion; so that chalk appeared a low conductor, then sandstone; but marble, glass, and fine earthenware were good conductors.

The preceding experiments were made for ascertaining the difference of power in conveying sounds between the varied of matter; and therefore, such forms as were at hand were tried; but, as it afterwards appeared that several of them were frequently used in the construction of walls of rooms, they suggested that the errors in providing for sufficient means of hearing proceeded as much from the materials employed as from the shapes of the rooms; so that, when very bad conductors of sound are used, the vibrations are not continuous throughout, but broken off at the walls, and the tension is not then sufficiently preserved for extending the voice much beyond the speaker, without great and almost uninterrupted exertion.

MEDICAL GAZETTE.

FRIDAY, NOVEMBER 18, 1850.

It appears to us that gentlemen who makes use of newspapers for the publication of a document in reference to scientific questions affecting public health, should be especially careful not to conceal or misstate the broad facts of the question at issue. We regret to perceive that a letter by Mr. R. Warington, dated "Apothecaries Hall, September 26th," in which the Government reports on the use of lead salts in the manufacture of sugar are criticised and condemned, is written in open violation of this rule. This document, which is rather remarkable for the *impresario* *vari*, has found a wide circulation through the *Times*, *Morning Herald*, and other newspapers. Of course it is to be presumed that the letter has been published by the knowledge and with the approval of the writer. Seven weeks have elapsed, and there has been no retraction or explanation of statements injuriously reflecting upon the researches and reports of the Chemical and Medical Commissioners appointed by Government, and consisting of gentlemen, not employed by solicitors to advocate only one view of a great sanitary question, but authorised by Government to exercise a free and independent judgment on the whole of the circumstances.

The letter to which we have above referred, is, in our opinion, well calculated to mislead those persons who are unacquainted with the nature of scientific researches, and to induce the public to believe that they may consume the patent sugars, prepared with the poisonous salts of lead, with actually less

risk to health than attends the consumption of sugar manufactured by the ordinary process.

The City article-writer of the *Times*, who appears to be completely deceived by this document, thus prefaces its publication by the following language:

"Having twice interfered in an affair of such importance, the Government were bound to bring it to a definite conclusion, and not to leave the public to find their way out of the alarm that had been raised by an examination and comparison of such casual statements as might chance catch their eye in the public press. But this, unfortunately, is now the position in which the controversy has been placed, and having inserted an analysis of the Parliamentary papers, we therefore give room to the following letter to the editors of the *patentees* from Mr. Robert Warington, the secretary of the Chymical Society of London, and Chymical Operator to the Society of Apothecaries, which throws out light on the entire subject. At the same time it is to be understood that the discussion, except so far as any necessary corrections may be concerned, should, for the future, be carried on through such professional channels as may be most appropriate for it."

We are sorry to have to express our conviction, that the whole question has been most unfairly dealt with in the City-articles of the *Times*. While Mr. Warington's letter and other documents in favour of the use of lead-sugar have been given *in extenso* in that journal, the analysis of the views of the Government Reporters referred to in the above extract, and published in the *Times* of September 12th, comprehends merely twenty-nine lines of extract from the *Chemical*, and sixteen lines of a summary of the *Medical Report*! In fact, even in the article in which these extracts appear, a much larger space is devoted to the views of the lead-sugar advocates, than of those who have reported against it. If, therefore, it rested with the City-article writer of the *Times*

* *Times* newspaper, Friday, October 18th.

and Mr. R. Warington, "the Chymical Operator to the Society of Apothecaries," the consumption of this sugar would be forced upon the British public in spite of their reasonable prejudices against the risk of slow poisoning by lead, and in the teeth of the *independent* Government reports. In order to counteract the one-sided views which have thus found the powerful advocacy of the *Times*, we think it right to analyse a document to which our contemporary has thus given a wide circulation.

MR. WARINGTON first deals with the *Chemical Report*, which was drawn up and signed by Professors THOMSON, GRAHAM, and HOFMANN. Apparently placing implicit confidence in the method of chemical analysis adopted by these gentlemen, the writer says:—

"It appears that the patent process, as directed in the specification of Dr. Scoffern, was followed out three several times by Professors Thomson, Graham, and Hofmann, without any trace of lead being found in the results, such results having been submitted to rigid analysis. The process is therefore quite unobjectionable in every respect on this evidence."

In a subsequent paragraph, however, we find the following statement:—

"The mode of analysis adopted by Professors Thomson, Graham, and Hofmann, for the estimation of the lead, which they state to be very easy and complete, and the sufficiency of which was tested, appears to me, judging from the published results, to be very unsatisfactory. For instance, we find it stated that one and the same quantity of treacle, made by the old process, yielded in one experiment 0·62 (gr.) and in a second 1·21 (gr.), or very nearly double the quantity. Surely a method of analysis that will yield so widely differing results from the same sample, cannot be received as complete or satisfactory."

No doubt the writer will be able to explain this somewhat conflicting opinion regarding the chemical skill of three gentlemen, two of whom are well-known

veterans in practical chemistry, by the fact that in the first case the result of their operations is in favour of his clients, and in the second case against them.

Let our readers, however, mark the disingenuousness of the statement impeaching the accuracy of the Chemical reporters. The chemical results are objected to, because "*one and the same quantity* of treacle yielded in one experiment 0·62, and in a second experiment 1·21 grains, or very nearly double the quantity." These decimals look very mysterious in the *Times* newspaper, and as the *quantity* of treacle which was the subject of experiment is not at the same time stated, the fact that the proportion by one result is double of that obtained by another, conveys the impression that Professors Thomson, Graham, and Hofmann, have made an awful blunder, and that their "mode of analysis, judging from their published results," &c., is "very unsatisfactory." "Surely," remarks Mr. Warington, with particular emphasis, "a method of analysis that will yield *so widely differing results* from the *same sample*, cannot be received as complete or satisfactory."

We must supply Mr. Warington's no doubt unintentional omission, and state for the information of our readers, that the quantity of treacle used in each experiment was *four pounds* (28,000 gr.), and that the awful difference in the quantity of lead found in the two analyses was no more than 0·59 grains—i. e., less than *six-tenths* of a grain, in operating upon this large quantity. Mr. Warington must have been perfectly aware that he was addressing newspaper readers, not well informed in decimals, or he would not have ventured to impeach the accuracy of the chemists upon so absurd a ground as this. Scientific men who might happen to see his letter, would not on

the other hand have it in their power to take any exception to his conclusion, because he had accidentally omitted to state that the quantity of treacle used was four pounds.* Now we must take leave to express a doubt whether the "Chymical operator to the Apothecaries' Society" would under the same circumstances have arrived at results differing less "widely" than these. Further, the treacle here referred to being derived from the old process, contains, according to Mr. Warington, carbonate and oxide of lead, arising from the use of leaden pipes and of moulds painted with white lead. The carbonate of lead is not a soluble salt: it may be, therefore, mechanically diffused through the mass of treacle in very variable proportion. There is, at any rate, no proof that every four pounds of a given specimen of treacle contains an equal quantity; and yet, in defiance of this palpable inference, and of his previous statement regarding the condition of the lead, the writer of the letter proceeds to impeach the chemical accuracy of such men as Thomson, Graham, and Hofmann! Mr. Warington assumes that the results should not have differed, although the difference was exceedingly small, when the bulky nature of four pounds of treacle is considered. In fact, as the lead-salt was in an insoluble and mechanically diffused form, it might have been inferred, *a priori*, that two specimens would not have given precisely similar quantities of lead. This objection, therefore, to the chemical results, is not only unfounded in fact, but calls for the stronger condemnation, because it is directly opposed to circumstances which must have been within the writer's knowledge. It was

* In a preceding paragraph wholly disconnected from that in which this absurd objection is made, it is stated generally that the results of the examinations, as detailed in the report, were obtained from four pounds weight of the sample operated on.

Mr. Warington's duty in such a case to have made analyses of common treacle; and then he would probably have found that in spite of the skill he could display, the results would have differed, perhaps even more than six-tenths of a grain on four pounds! Until he had gone through this special research he was not entitled to take exceptions to the results of others,—exceptions which, had the whole of the facts been properly and candidly stated in his letter, would have been found to tell strongly against the accuracy of his judgment.

To us it appears that the Chemical reporters have been most unfairly dealt with by the patentees. We learn from the report, that they obtained "by the courtesy of Messrs Goodhart, sugar-refiners of Limehouse, who were working under the new patent, *properly authenticated samples of refined sugar of ten different operations*, with one sample of bastards and two samples of treacle, *all produced by the new process*."* These samples were sent to the Chairman of the Board of Inland Revenue, with a letter dated March 30th, 1850, from which the following is an extract:—

"We have to remark that, owing to the defective nature of the filtering apparatus after the *gassing operation*, the liquor was at times turbid (though we have since remedied that defect, and obtain constantly a brilliantly bright liquor); but it is probable that in some of the sugars, as per samples herewith sent, a portion of sulphites may be detected, but we believe no other traces of lead, further than may have been caused by contact with leaden pipes and cisterns, which we, in common with most other sugar-refiners, make use of, as also white lead in painting the iron moulds."

This extract, it will be perceived, involves a very cleverly expressed reservation on the part of the manufacturers. Had the results turned out

* Chemical Report, page 2.

favourably, and no lead been discovered well and good: we should have heard no more of this letter or of the defective nature of the filtering apparatus. As it is, we have no information whether the sugar from which these ten loaves, &c. were taken—the result of defective filtration—was sold to the public, or destroyed as unwholesome after the publication of the Chemical Report! The adverse nature of the Government Reports, however, has caused this letter to be brought into prominent notice. Thus Mr. Warrington condemns these Reports as being based on the examination of products admitted to have been obtained by the use of defective filtering apparatus! He says—

"The products of the process of which the patent forms a part, as obtained from parties who had been working only for a short period, are then experimented on. Now, it must be obvious that the first introduction of a new process, however perfect, and however suitable to the large scale, will at first, to a certain extent, be attended with difficulties in its practical working out. The evidence of Mr. Goodhart's letter proves this to be the case in the present instance. . . .

"No examination appears to have been made of the syrups obtained by the new process before they were brought in contact with the leaden pipes, cisterns, and painted moulds, alluded to in this letter; and all the lead found by Professors Thomson, Graham, and Hofmann, in these samples may really have arisen from this source; and if so, a great injustice may have been done by the Report from want of proper circum-spection.

"In regarding, therefore, the results obtained by Professors Thomson, Graham, and Hofmann, from the samples procured under these circumstances, it seems to me that a much nearer approach to accuracy will be attained by taking the minimum weights as evidence of the working out of Dr. Scofield's process, which process they themselves report as perfect. The results, then, will stand thus:—In loaves, no lead; in bastards, 0.48; in the treacle, 0.87; or, by comparison,—

	Old process.	New process.
Loaves	0.05	none.
Bastards	0.25	0.48
Treacle	1.21	0.87

Mr. Warrington must be perfectly aware that the Government was only desirous of having what the patentees considered fair samples of their sugars submitted to analysis. The manufacturers were allowed to send their specimens; and it appears from their letter that the ten loaves sent as samples were derived from different days' work at various periods, from December 31st to March 13th. Hence the defective filtering apparatus appears to have been worked during a quarter of a year. Of the other samples, one of treacle was marked "to be passed through a bed of charcoal." The analysis was commenced about the latter end of March, and the Report was not presented until the 28th of the following June. The manufacturers and the patentees, without making any remonstrance, or proposing to substitute perfect for what they have since called imperfect specimens, had, therefore, allowed the chemists to proceed with their elaborate researches during the long period of three months; and it was only when they found the results adverse that they fell back upon the letter which accompanied the samples to show that they were not fairly-taken specimens of the new process, and the results were therefore untrustworthy! That manufacturers deeply interested in the pecuniary proceeds of a patent should take this sinuous course is not surprising, but we must express our astonishment that they should have found a gentleman, occupying Mr. R. Warrington's situation at Apothecaries' Hall, to aid and abet them—nay, to justify them in such a proceeding. Let us suppose that Government had referred to him the analysis of certain drugs alleged to be adulterated: he is allowed by the drug-merchant to take samples with the knowledge that he is

to submit them to chemical analysis, and report on them for the information of Government. After having been engaged *three months* in his operations, and having made a report showing no disposition to prejudice the merchant, he is then coolly informed, upon the authority of some "chymical operator" who has not taken the pains to analyse the drugs, that his analysis and report are worth nothing, because the samples had become contaminated by some defective drug-grinding apparatus. It is beyond all question certain that, had the Chemical and Medical reports been favourable to the patentees of the new sugar process, we should have heard nothing of the defective filtering apparatus, &c. The fact that they allowed the specimens to remain three months in the hands of the chemists, either entirely does away with the plea now put forth in their favour by Mr. Warington, or in future there can be no *bona fides* in similar scientific investigations.

Let our readers observe the results of Mr. Warington's ingenuity in asserting that the *minimum* weights of lead contained in the patent sugar may be taken as a much nearer approach to accuracy. Thus, while he represents that the loaf-sugar of the patent process contains *no lead*, the report from which he draws this conclusion states in figures, that out of ten samples *nine* actually contained lead—one sample as much as a grain in four pounds! Thus, according to Mr. Warington's mode of dealing with chemical facts, if you find lead in nine specimens out of ten, it is quite fair to tell the public, through the newspapers, that there is *no lead* present!

With respect to the loaf-sugar of the old process, Mr. Warington's table represents it as containing 0.05 grains of lead in four pounds. This is a complete misrepresentation of the statement of the Chemical reporters, which we now quote from page 2 of the Report:—

"No lead whatever appeared to be present in four lbaves of sugar refined in different operations by the ordinary process: at least, no much as is equivalent to 1-20th of a grain (0.05 grain) of sulphate of lead could not be present in four pounds of any of these samples."

Let our readers compare this statement with a representation of their facts and figures as given in Mr. Warington's table. He describes them as actually finding 05 grains of lead in four pounds of loaf-sugar, when they positively state that they found *none*, and that there could not have been present so much as Mr. Warington assigns as the average. This is what Mr. Warington considers to be "a much nearer approach to accuracy," we should describe it as the reverse. The same sort of free and easy dealing runs through the other series of figures. Thus, while in the extract from his letter Mr. Warington asserts that the *minimum* weights will afford a much nearer approach to accuracy, he gives the benefit of this estimate only to the patentees, upon the principle, probably, that any amount of inaccuracy will answer for the sugars of the old process, and the readers of the *Times* would not probably discover that the *maximum* weights in one column were compared with the *minimum* weights in another.

Thus we find in the Report that the bastards and treacle prepared by the old process gave the following weights of sulphate of lead:—

	Max.	Min.	Mean.
Bastards	0.25	0.19	0.22
Treacle	1.21	0.62	0.91

It will be perceived by reference to Mr. Warington's figures that in treating of the old process he takes for comparison the *maximum* weights of lead salts; and in dealing with the new process he selects the *minimum*. The old process is entitled to fair play; but it certainly does not get it at the hands of Mr. Warington, or of the City-article writer of the *Times*. They are determined that the public

shall swallow the lead-sugar; and while one cooks the results the other serves them up. We are sorry to spoil the cookery; but in a scientific question of this kind we consider it to be our duty to watch over the interests of the public, although the remarks we feel bound to make may damage an ingenious but dangerous application of chemical science.

After this demonstration of Mr. Warrington's mode of dealing with the *facts* and *figures* of a Chemical report, we think we need hardly dwell upon the other parts of his letter. There is either the same want of fair dealing, or there is blundering throughout. Facts are either misstated or mistaken. In reference to the *Medical* Report we find the following remarks:—

"The report of the medical jurists, Drs. Pereira, A. Taylor, and Carpenter, is of no value whatever, inasmuch as it is based on fallacious grounds; for they state, 'Our investigation practically resolves itself into the inquiry, whether 1·261 grains of metallic lead contained in a salt of lead, capable of becoming dissolved by the juices of the alimentary canal, swallowed weekly for probably many months, are capable of producing serious injury to health?'

"Now there is no evidence whatever in the report to show that the lead stated to be contained in the samples examined, was in such a state as that required by these gentlemen, and on which supposition their report is entirely founded; nay, worse,—they adopt the very extreme result obtained from a sample of treacle which was stated in writing by the manufacturer to be objectionable from a defect in the working of the filtering apparatus; and on this assumption they call in question the chemical accuracy of the patent process."

We think it a somewhat droll proceeding on the part of the patentees to apply to a gentleman known only as a pharmaceutical chemist for his opinion on a subject which presupposes a *medical* education, and requires a knowledge

of physiology, pathology, and toxicology. That they could find no better authority to apply to in reference to a question of chronic poisoning by lead than a gentleman who has probably never seen a case, and whose studies are confined to pharmaceutical chemistry, leads to the inference that the opinions of members of the medical profession must be adverse to them. The result may easily be foreseen. In the *Medical* Report, as we read it, the quantity of lead in the patent sugars is calculated as metal to avoid all quibbling about the actual state of the salt of lead in the sugar, which appears to be just as mysterious to Mr. Warrington and the patentees as to the reporters. We know of no salt of lead which is not more or less soluble in the secretions of the alimentary canal; when dissolved it becomes absorbed, and when absorbed it is liable to affect the system injuriously. Mr. Warrington appears to think that the lead is supposed to be swallowed in a *metallic* state in the sugar; but we do not gather this from any part of the Report. It seems to be left as an open question, whether it be in the state of sulphite, sulphate, carbonate, or undecomposed acetate? To affirm that the three former are not in a state to be dissolved by the juices of the alimentary canal, merely because they are not very soluble in *water*, would display great physiological ignorance, and show that the person was not qualified to give any opinion on the subject.

The objection that the treacle which yielded the maximum of lead was the product of a working with defective filtering apparatus, we have already disposed of. It was the duty of the parties not to have sent for analysis, specimens of sugar or treacle which they considered defective, or to have withdrawn them, for which there was ample time. The Reporters, in conscientiously performing the duty en-

trusted to them by Government, of stating the probable effects of the patent sugars on health, were bound to take *extreme results*. There was nothing to show that the maximum weight of lead might not be frequently present in patent treacle sold to the public, who have no means of ascertaining whether this article of food has or has not been "passed through a bed of charcoal." To have reported only on the probable effects of a *minimum*, or even of an average weight of lead, would have been undoubtedly more favourable to the patentees; but it would have been a breach of duty, in a sanitary point of view, since the patentees could give no satisfactory security that the weight of lead in the treacle should not exceed the average and reach the maximum.

Such is the letter upon which Mr. Warington and his coadjutors would recommend the general use of poisoned sugar. The City-article writer of the *Times*, without taking the trouble to compare the letter with the Report, adopts the whole of Mr. Warington's statements, including the distorted facts and erroneous figures, and thinks that an attempt has been improperly made to stifle a valuable discovery. It is his opinion that a case is made out for further inquiry. We trust that the Government will adopt the suggestion, if only to expose the unfair means which have been resorted to in order to support a bad case.

It is incontestably proved that a salt of lead is liable to be left in the sugar as manufactured. It is quite possible, as the Chemical reporters assert, "that the lead may be removed from the sugar to a point beyond danger, provided the operations are *constantly watched by a person competent to apply the necessary chemical test of purity to the products*." The great practical question, as it affects the public, is not the chemical accuracy of the process as it may be conducted in

a chemical laboratory, but, to use the language of Mr. Wood, as it may be carried on "on a large scale, and by *common workmen*, who may not be sufficiently impressed with the necessity of *entirely freeing the products from any trace of deleterious ingredients*." The syrups are strongly impregnated with a poisonous salt of lead; under proper and skilful superintendence the whole of this lead may be removed from the sugar. But is the health of the public to rest upon a contingency like this? When a general colic has spread throughout the land, and has affected all, or even a large number of the consumers of sugar and treacle, it will be no satisfaction to turn to Mr. Warington's figures, and to find that, according to his calculations, they ought not to have suffered, because *one* patent loaf out of *ten* contained no lead, and because the *minimum* found in patent treacle was less than the *maximum* existing in sugars of the old process!

To banish these fears from the public mind, the patentees say that the sulphite of lead left in the sugar is not a poison; and, in support of this assertion, they quote the opinions of two gentlemen who, so far as we can ascertain, have had no experience whatever on the subject of lead-poisoning—namely, Dr. GREGORY and Mr. WARINGTON. The former gentleman performed a set of experiments on rabbits, for the inconclusive nature of which we refer our readers to some remarks made elsewhere.* Without attempting to determine whether the sulphite of lead is soluble in the *secretions of the stomach*, Dr. Gregory alleges that it is *not poisonous*, owing to its excessive insolubility in *water*. In the next sentence of his letter, the carbonate of lead, which is also remarkable for its excessive insolubility in water, is described

* See MEDICAL GAZETTE, August 30, p. 378.

by him as the "truly poisonous compound of lead!" Mr. Solly has corrected the fallacy contained in this inconsistent statement.* We are also able to supply facts which show that if, according to Dr. Gregory's experiments, rabbits are fattened, dogs are liable to be poisoned by sulphite of lead.† In the Parliamentary papers before us there is a letter from Dr. Gregory, announcing that sulphite of lead is "perfectly innocuous, and as harmless as so much chalk would be."‡ Mr. Warrington has no experience of his own to offer, but he gives his opinion that Dr. Gregory's experiments satisfactorily show that sulphite of lead is an innocuous substance. On this we shall simply remark, *Ne auctores ultra credidas*.

One strange argument which has been brought forward in favour of the lead-sugar process we must briefly notice in bringing this long article to a close. Some sugars of the old process have been found to contain lead in small quantity, arising from the use of leaden pipes and cisterns, as well as moulds painted with white-lead. We have the admission of Messrs. Goodhart, in their letter already quoted, that they, the patent sugar-makers, employ these leaden articles of apparatus in common with other sugar-refiners.§ Hence it

has been inferred that, as lead-poisoning already goes on, to a certain extent, in the consumption of ordinary sugar, it is only reasonable to allow it to go on to a still greater extent by the encouragement of the use of the patent sugar! We demur to this inference, and contend that, so far as it may be practicable, rules should be enforced to prevent the introduction of lead, whether accidentally or designedly, into any description of sugar.

THE CHOLERA IN JAMAICA.

THE most recent intelligence from the West Indies states that the greatest excitement prevailed in Kingston, Jamaica, in consequence of a case of cholera having occurred in that city. At the opposite port, Port Royal, during the few days previous to the steamer's departure, a number of cases had occurred, and about twenty proved fatal. The case in Kingston is described by one of the newspapers as being the "malignant Asiatic cholera;" but it is denied by the medical testimony, which declares that the patient died of a "form of cholera." In Kingston the civic authorities, who had previously been very inactive, had become very vigilant. Meetings of the Board of Health had been held, and a sanitary committee, appointed by the corporation, met every morning. No official returns were made of the cases in Port Royal; but, notwithstanding accounts which reached Kingston were greatly exaggerated, it was an ascertained fact that the cholera had appeared there, and the inhabitants were in the greatest excitement and alarm in consequence. The governor of the island had sanctioned the employment of the convicts in the Penitentiary on the roads of the city, for the purpose of keeping clean the streets and lanes, and the Commissioners of Public Accounts voted £1000 for the purpose of effectually carrying into effect the various sanitary regulations made and to be made. Judging from the form the disease had assumed, and the few cases that had appeared, it was hoped that its ravages would not be great.

* See Pharmaceutical Journal, October, p. 248.
† See in the present number, page 856, an account of the recent experiments of Mr. Edmund Greaves.

‡ Dr. Gregory goes even farther than this, and says—"I should have no objection personally to use the sugar made by Dr. Scoffern's process, even if some sulphite were accidentally mixed with it." We trust that Dr. Gregory will not thus offer himself as a chemical martyr on the altar of science. The fate of the dogs experimented on by Mr. Greaves (see page 856) holds out a wholesome warning.

§ Admitting this to be a correct statement, the patent sugar should contain the amount of lead found in sugars of the old process *plus* that which is introduced by the employment of salts of lead, and not removed by filtration. This affords another very curious illustration of Mr. Warrington's mode of dealing with figures. It will be seen, on reference to his tables, that the patent treacle, instead of containing *more*, actually contains *less* lead; the difference being

0·34 grs. Thus we arrive at this remarkable inference:—By the use of lead-salts in refining patent sugar, you not only get rid of the whole of the lead thus introduced, but actually remove about one-fourth of that which all sugars take up from leaden apparatus, &c.!

Reviews.

Illustrations and Inquiries relating to Mesmerism. Part I. By the Rev. S. R. MAITLAND, D.D., F.R.S., F.S.A., sometime Librarian to the late Archbishop of Canterbury, and Keeper of the MSS. at Lambeth. Pamphlet, 8vo. pp. 82. London: Stephenson.

Mesmerism Tried by the Touchstone of Truth: being a reply to Dr. Ashburner's Remarks on Phrenology, Mesmerism, and Clairvoyance. By GEORGE CORFE, of Middlesex Hospital. Pamphlet, 8vo. pp. 44. London: Houlston and Stoneman.

THE authors of these two pamphlets admit the *facts* of mesmerism—that is to say, the production of certain phenomena known as mesmeric. Thus Dr. Corfe, in his letter to Dr. Ashburner, says:—

"I cannot say that I deny the facts which you adduce. . . . Now if these are facts, then no one can doubt but that there is a power in operation which is not in the possession of every mortal, and that power is supernatural, and beyond finite control. Such I deem to be the fact, unless the whole relation of mesmerism is to be resolved into a tissue of lies and of fraud, which I cannot agree to." (p. 17).

And in like manner Dr. Maitland states his conviction, "that what are called the common phenomena of mesmerism—by which phrase I mean those phenomena (some of them, in one sense of the word, very uncommon) which have been concurrently maintained by mesmerisers in various countries for more than half a century—are realities;" and "that they are, both in themselves and in their indications, very serious matters, and such as demand the deep and earnest attention of all who know their existence" (Preface).

The manner, however, in which the two authors proceed to the inquiry of the nature and tendency of mesmerism, differs widely. Dr. Corfe, the author of a useful practical work on the *Physiognomy of Disease*, denounces the whole of the mesmeric phenomena as the direct work of the Devil, and proceeds to enlarge on its evils as earnestly, as warmly, and as energetically as zeal and the fear of God can urge him. Dr. Maitland, a divine and an ac-

complished scholar, knows to us as the learned author of that most interesting work, "The Church in the Catacombs," proceeds more deliberately to state the facts, and to inquire into their character and tendency. The professions seem here, for the nonce, to have changed places: the physician is found vehemently consigning mesmerism and its professors, on religious grounds alone, to the paternal charge of the Father of Lies; while the clergyman is found dispassionately and logically arguing, from certain known premises, to their legitimate inferences. It is to the work of the latter, on this account, that we shall principally direct our readers' attention.

Dr. Maitland cites a series of cases from the *Zoist* in "illustration" of clairvoyance, without in the least casting any doubt upon their truthfulness, as will be seen by the following extracts:—

"If the reader has made up his mind to believe or disbelieve, without regard to testimony or evidence, either side of a question which has been discussed with disgraceful bitterness, ignorance, and folly, I am not anxious about his approbation; if not, I hope he will acquiesce in the propriety of this course, and will also understand and approve the motives which lead me to take the illustrations for this section (clairvoyance) exclusively from the reports of cases published in the *Zoist*. That periodical work is the principal organ for the diffusion of information on the subject, and it is countenanced and contributed to by the chief patrons and practitioners of mesmerism. It has not yet been seven years in existence, and all the cases to which I refer in this section have occurred within that period, and in our own country. The reader, therefore, who wishes to verify my transcripts, may do it by reference to one English book; and if he likes to go a step farther, and inquire respecting the genuineness and authenticity of the stories themselves, he may in a good many cases, without much trouble, inquire on the spot, and put his questions to the parties actually concerned." (p. 1).

Most of these facts are familiar to our readers: they are offered by the author as "illustrations," not as "proofs." We do not, on our part, doubt the genuineness of the narrative; but we cannot entirely exclude the possibility of deception on the part of the performers in all cases, remembering the exposure of Alexis and others by

DR. FORBES AND SHARPEY. On this point, however, we shall not now press, but shall be content to admit all that Dr. Maitland requires. We pass at once to the consideration of mesmerism "volition," Dr. Maitland's account of which we shall present in the author's own words:—

"That one person should be able, by the simple exercise of his own will, to influence the will, alter the state, and regulate the actions of another—of another, too, who is distant, and altogether unconscious of being the subject of such influence—is certainly very hard to believe, and constitutes one of the most wonderful of the alleged facts of mesmerism.

"It has, however, been asserted, and strenuously maintained, for more than half a century, by persons whose statements are entitled to attention. Whether they are right or wrong in all that they say I am not undertaking to decide; and, indeed, it is not my purpose at present to inquire. My object, and my earnest desire, is to call the attention of sober and reflecting persons to what is a plain and indisputable truth—namely, that this alleged fact is now maintained as a reality by such a weight of character, and such a body of evidence, and is assuming a form of such importance, that it ought to be investigated by those who, though they may have no particular taste for such inquiries, have some fear of God before their eyes, and some concern for the welfare of their fellow-creatures."

This "submission to the overpowering influence of the will of another," Dr. Maitland investigates in the cases recorded by mesmerists. We quote one or two of the shortest of the instances adduced. It appears to us to be an important fact, and one worthy of note, that they are believed by such an inquirer as Dr. Maitland:—

"When urged to look at any thing, she expressed the greatest repugnance to do so; and it was only at the reiterated command (mental, be it observed) "of the mesmerizer that she aroused herself to the necessary effort. At these times her whole deportment was that of a person who wished to rest, yet who, by some external force, was compelled into exertion. No exorcised spirit could have done its work more grudgingly; and, like the enchantress evoked by Odin, she continually entreated to be left to repose." (Townshend's Facts in Mesmerism, p. 46.)

"She responded to the excitation of the phrenological organs, and felt obliged to obey the will of the mesmerizer up to the

point of following him about the room; but if she were commanded to do anything very repulsive to her feelings, she became awake instantly and suddenly." (Ashburner, in *Zoist*, No. xiii. p. 182.)

The next extract we quote is from the pen of the lady in whom the phenomena are said to have occurred:—

"After being thrown into my usual state, Mr. Nixon retreated a few steps from me, when I felt a strange sensation of uneasiness, and my arms stretched out, pointing whichever way Mr. Nixon moved; my mind all the while active and clear, though the power to control my movements was entirely gone, and I felt drawn irresistibly, as the needle by the magnet. After a time my uneasiness increased, and I rose and followed my mesmerizer, my eyes still being closely shut." (*Zoist*, No. xiii. p. 238.)

The same young lady also puts on record the following:—

"I was speedily under the mesmeric influence, my body and senses subdued and under control, but my thoughts, as usual free and clear. . . . This evening I followed my mesmerizer unerringly through the room with closed eyes, and answered correctly to pressure over several of the organs of the head. When an organ was touched over I felt irresistibly impelled to follow the indication, though perfectly aware of what I was doing: for instance, Mr. Nixon, meaning to touch Firmness, happened to touch Veneration, and I fell on my knees, my thoughts turning to God and heaven. When Firmness was really touched I was compelled to draw myself up to my full height, and aspire, as it were, to reach the very ceiling." (*Zoist*, No. xiii. p. 239.)

We cannot quote the whole of this passage; we leave our readers to make their own comments thereon, when we have laid before them Dr. Maitland's views. With reference to the mesmeric states of "attraction" and "attachment," Dr. Maitland quotes from Dr. Elliotson:—

"I have invariably observed, without a single exception, in all my mesmeric experience, from the time of the Okeys, in 1837, to the present day, that the mesmeric state has, even if characterized by affection, and the most intense affection too, apparently nothing sexual in it; but it is of the purest kind, simple friendship, and indeed exactly like the love of a young child to its mother; for it seems characterized by a feeling of safety when with the mesmerizer, and of fear of others. Those who think they have seen anything else must have seen with

the eyes of a prurient impure imagination, unless the unjustifiable experiment of mesmerising Amateurs has been made."

On this Dr. Maitland very properly observes:—

"Could we be sure that persons who have unjustifiable designs would abstain from unjustifiable experiments this would be perfectly satisfactory—but what an 'unless!'"

In a note on this passage Dr. Maitland also remarks:—

"Very probably that 'unless, &c.' is just what alarmed Dr. Mayo, and will alarm others,—not the less, because on this repetition, though the candour and honesty of the author induced him to include the 'unless,' he considered the ' &c.' too obvious to require explanation, or even statement. Certainly that one word from Dr. Elliotson has startled me more, and has more weight, than all that I have heard from the opponents of mesmerism."

Again:—

"One is tempted to ask whether if the clairvoyante of whom we have just read, instead of being told to blow out the candle, had promised to throw herself out of the window, or stab one of the company, she would have found that 'the impulse was irresistible;' and, if so, whether a promise made in private to fire the house at midnight, or become the instrument of any other crime, would have been as punctually performed. . . . Such power, even in the hands of the wise and virtuous, is tremendous; but is it, or can it be, confined to them in the days when science is the idol, and its fervent worship consists in popularising its discoveries? I know, but it does not entirely remove my fears, that no harm is likely to come of even this, unless some of the sedate million should make unjustifiable experiments." (p. 41.)

That these "unjustifiable experiments" have been made is not only not denied, but avowed, with reference to another line of magnetic investigations.*

Dr. Maitland next inquires, respecting his "illustrations,"—Is all this true? And his answer, if we rightly understand him, is to the effect that not only is it all true, but it is not the whole truth; that still more startling facts might be related.

* "Point to Ametivness, and the woman, if her organs are at full, is unable to control her actions; she burns with desire." See note by Dr. Ashburner, in his translation of Reichenbach's *Researches on the Dynamics of Magnetism*, &c.

"Is it supernatural," the author asks, in the next place: we quote his answer:—

"I am content on the present occasion to treat of mesmerism as merely the exercise of a power which belongs naturally to men, or to one man in a given number—a power which (so far as that can be said of any which he possesses) he can use according to his own will, to produce certain effects on other men, independently of all that is external to himself—a power, let us suppose, not more visible, or ponderable, or explicable (but at the same time not more supernatural or miraculous) than the muscular energy and mental volition which enable one man to knock another down. I am content to take this merely as an hypothesis, in the belief that it will save trouble and not injure truth." (p. 47.)

What is it, or what is it like? forms the next inquiry. The answer involves the consideration, at some length, of the ancient divinations, magic, witchcraft, familiar spirits, &c. mentioned in the Scriptures, with which the author identifies its phenomena. We cannot abridge this part of his investigations without damaging the author's argument; we therefore refer our readers to the original pamphlet, where they will be rewarded by the fruits of the author's erudition and biblical knowledge.

We conclude our remarks on Dr. Maitland's pamphlet with his observation on a "most interesting and important question," and one which, observes the author, "if I did not know that it engaged the deep and anxious attention of others as well as myself, it would not be worth asking—Is mesmerism divisible?" Here, again, we prefer giving the author's answer in his own words: and if we seem to occupy more space than mesmerism would lead them to suppose it deserving, we may remark that the tone and the spirit of Dr. Maitland's pamphlets, as well as the conformity of his views in certain respects to our own, demand that, for the interest of truth, we should bring it prominently under their notice.

To state, then, our author's answer:—

"For the convenience of writers, and readers, and talkers, who are supposed to understand one another, a phraseology has been adopted which seems to assume that it is (divisible); and without any one's pretending to draw a strict line of demarcation, we are accustomed to read and speak of the 'higher' and 'lower' phenomena of mesmerism. That the phenomena thus

popularly divided do, in many cases, exist separately there is no doubt. But are the things essentially distinct, or only different parts, or degrees, of the same thing? We might even ask, "What security has the patient when he puts himself in the hands of the mesmerist against such a subjugation as amounts to a voluntary abandonment of the power of reason with which God has endowed and entrusted him? and what security has the mesmeriser (who adopts the Bible) that he is not usurping that very influence over his fellow which God has forbidden him to exercise?" If it be said, "God hath given men these powers, and are we not to suppose that he meant them to be used?"—the plain answer is, He has given men power to commit murder, theft, and a variety of things which he has forbidden; and that, not only in the gross form of the act itself, but as to those courses, practices, and dispositions which lead to it." (p. 68).

"In the meantime, I hope I am not wrong in putting forth a few words of excuse, or at least of deprecation, on behalf of those who hesitate to take an active part in promoting the use of mesmerism on what philosophers may think foolish and superstitious grounds. We do not consider ourselves as more inhuman than those whom science has rendered intelligent, virtuous, and happy. We think that while we are withheld by what others may consider, and what may actually turn out to be, unfounded fears, from actively promoting the practice of mesmerism, it is unjust to hold us up to public odium as persons who 'dislike to see a racking pain removed by it; to see the feverish, sleepless invalid, enjoying a balmy slumber by its aid; to see the nervous, excited patient, restored to comfort and repose.' For myself, at least, I know that I may honestly disclaim such feelings; and I shall be most grateful to any one who may be able to remove the scruples which I feel bound to express, by fairly meeting the question which I have placed at the head of this section, and distinctly showing that therapeutic mesmerism is separable from, and no part of, the curious art of soothsaying and divination which busies itself in the banker's shop or the pawnbroker's cellar" (p. 70).

Dr. Maitland, we consider, has here brought mesmerism to the "touchstone of truth," to the test of the standard of right or wrong. We thank him for this first instalment of his inquiry, and hope that he will not long delay the remaining portions.

We must not, however, conclude without bestowing a few more words on Dr.

Corfé's pamphlet. We honour the author's religious principles, but would fain hear less loudly the sounds of the "drum ecclesiastic." Dr. Corfé's zeal carries him sometimes a little beyond the limits of the apostolical injunction, which says, "let all your things be done with charity," and "let your moderation be known to all men." The following short extracts will justify our censure of Dr. Corfé's vehemence:—

"The spirits of phrenology and mesmerism are twin devils, co-partners, fraternal spirits of uncleanness." (p. 25.)

"You appear as a disciple of Mesmer and of Gall, and an apologist for the Devil, who is the author and abettor of both clairvoyance and of phrenology." (p. 24.)

But we should also, in justice to Dr. Corfé, cite some of his more deliberate and calmer statements with reference to the effects of mesmerism:—

"I firmly assert, that throughout the whole period of nine years, during which mesmerism was more or less practised by yourself and Dr. Wilson, whilst holding the office of physician to this charity, I never once saw or heard of an instance of cure effected through its agency; but, on the contrary, I have witnessed many serious evils result from its employment." (p. 16.)

Among these "serious evils," we quote the following:—

"I never saw nor heard of anything of the sort go forth but what was indecent, disgraceful, and injurious. All the patients have unequivocally expressed themselves worse, where real disease existed; and where nervous disorders only were present, the mind has been worked upon, the lascivious passions have been excited, and the will, unable to control the animal desires, has lost its balance, and the patient has been momentarily stupified by the 300 or 400 passes to and fro before the eyes, but only to awake in a more libidinous state than before: and this has sent them, sooner or later, to wander the streets to gratify their lust, and thus they have become open prostitutes." (p. 21.)

The authors before us, as we have already remarked, unite in admitting the facts of mesmerism: they differ in its source, but they coincide in its uselessness and danger. And surely, in the present utilitarian age, facts which present nothing to attract but their marvellousness, must ere long come to be disregarded and despised; or, having a potency of some kind, but not for good, must be dreaded and shunned by

all who, looking to the issue of their actions, would not lightly tamper with the responsibility and free agency of their fellow men.

The Elements of Materia Medica and Therapeutics. By JONATHAN PEREIRA, M.D., F.R.S., F.L.S., &c. Third Edition. Vol. II., Part I. London: Longman. 1850.

As many inquiries have been made of us respecting the publication of the second volume of this well-known and valuable work, we take an early opportunity of announcing that the volume will be published in two parts, and the first part is now before us. This part is a goodly volume in itself, as it covers 639 pages, and contains 173 illustrations, without including an admirable steel-engraving representing the microscopic characters of different varieties of starch.

The second volume is devoted to the *Organic Bodies of the Materia Medica*, and the present part comprises the history and properties of a large variety of vegetable substances which are extensively employed, either as articles of food, or in medicine. It is unnecessary to enumerate these, as we are now dealing with a standard work in its third edition. We shall only remark that every article bears witness to the industry and indefatigable research of the author. Instead of being merely the elements of materia medica, it constitutes a complete encyclopædia of this important subject. The student of physiology, pathology, chemistry, botany, and natural history, will find herein the most recent facts and discoveries in his favourite branch of study, and the medical practitioner will have in this work a safe guide for the administration and employment of medicines.

The Natural History of the Varieties of Man. By ROBERT GORDON LATHAM, M.D., F.R.S., &c. &c. 8vo. pp. 574. London: Van Voorst. 1850.

THE writings of Dr. Prichard have given an impulse to ethnological researches that has been productive to them of great and, we trust, permanent benefit. Physiologists have learnt that ethnographical distinctions are not to be traced exclusively, or even chiefly, in variations of physical conformation, but that their most correct data are to

be discovered by the philologist. It has hence resulted that a vast mass of new matter has been rapidly accumulating since the date of Dr. Prichard's labours, recent though they be. The Ethnological Society of London has been actively employed in concentrating this later information, and has embodied much thereof in its "Proceedings." We may observe that the author of the work before us is a prominent member of that Society, and has the reputation of being one of the most eminent philologists of the present day.

The present treatise, from the name of the author, may be expected to possess the attribute of originality, so far as the working up of a large amount of material, collected for the most part by the labours of others, may admit of originality. The readers of the book will not be disappointed in their expectations on this point. A different classification to that of his predecessors has been adopted by Dr. R. G. Latham, the primary divisions of the varieties of the human race being limited by him to three—the Mongolian, the African, and the European. The terms by which these are expressed by Dr. Latham are: Mongolids, Atlantids, Japetids. It is not in treating of the primary divisions alone that the particular features of this work consist.

It would carry us beyond the limits which we can afford on the present occasion if we were to follow the author through all his subdivisions; but we may direct attention to the introductory observations, in which Dr. Latham expounds the principle of their formation. Preceding the consideration of each subdivision and variety is a tabular statement of its chief points—e.g., physical conformation, languages, area, locality, political relations, religion, mode of writing, numbers, synonyms, &c. &c., according as each presents peculiar features of importance.

Dr. Latham concludes his volume with a short notice of the general character of the science of ethnology, in a series of general and special apothegms.

The author remarks, that "a subject that a single book, however encyclopædic, can represent, is scarcely worth taking up in earnest." The work before us, although deserving the title of "encyclopædic," as those who peruse it will discover, certainly does not fully repre-

sent the entire subject. Classification is the chief end of this work; and, having thus brought forward his classification, we doubt not that Dr. Latham will prosecute his philological researches to the filling up of the outline which he has herein so ably and distinctly traced. The materials abound; and from one so skilled in languages, and so competent in every respect to the task, we hope that perseverance and industry will in due time produce that which we anticipate—a complete modern work on ethnology. In the meantime the present volume cannot fail to be most acceptable and useful to the students of one of the most interesting branches of knowledge.

Prophylaxis; or, the Mode of Preventing Disease by a due appreciation of the grand Elements of Vitality—Light, Air, and Water: with observations on Intramural Burials. By EDWARD BASCOMBE, M.D., &c. Pamphlet, 8vo pp. 29. London: Higley.

THIS pamphlet was "intended to form part of a work which will be shortly published, entitled 'A History of Epidemic Diseases from the Earliest Ages. 1491 years before the Birth of Our Saviour, to the Present Period, &c.'" The interest excited by the outbreak of cholera at Tooting induced the author to publish at that time "his ideas as to what should form the groundwork—the very basis of all sanitary measures." Dr. Bascome cites from historians many instances of the occurrence of disease and death, from deficiency of the "grand elements of vitality," and enforces the paramount importance of their supply in purity and abundance, as the "basis of all sanitary measures."

Lectures on Inflammation. By JAMES PAGET, Professor of Anatomy and Surgery to the Royal College of Surgeons of England, Assistant-surgeon to St. Bartholomew's Hospital, &c. Pamphlet, 8vo. pp. 57. London.

THESE Lectures have already appeared in our pages. Our readers are, therefore, well acquainted with their contents. They have been extensively transferred to the pages of other periodicals, and are admitted to be among the most valuable of the latest contributions to pathological literature. We now merely announce their publication in a separate form.

Proceedings of Societies.

MEDICAL SOCIETY OF LONDON.

Nov. 1, 1850.

DR. J. R. BENNETT, PRESIDENT.

Health of London during the six months terminating September 28, 1850.

DR. WEBSTER, the author of this paper, stated that the health of London had been recently very satisfactory compared with ordinary seasons, but still more so when contrasted with last year. Thus, during the six months terminating the 28th of September, 22,816 persons have died in London, instead of 40,117 in the parallel season of 1849, being a diminution of 17,301 deaths, or 43.12 per cent. in favour of the present compared with the former period. This great difference is chiefly owing to the very diminished mortality by cholera; only 96 individuals having died from that cause, instead of 13,115 during the same months of last year. Diarrhoea and dysentery have likewise proved less fatal; the deaths by those maladies being 1459, instead of 2946 in the same six months of 1849. Measles, scarlatina, and hooping-cough, have also prevailed less severely than previously. Besides these complaints, typhus, which, in the second and third quarters of 1849, caused death to 1222 individuals, was fatal in only 900 instances during the past six months. Phthisis, pneumonia, and bronchitis, also come within this category; likewise convulsions and erysipelas; 168 patients having died of the latter disease during the recent season, instead of 213 in the same six months in 1849. Notwithstanding the diminished total mortality of London during the period embraced in Dr. Webster's reports, several complaints have exhibited an increased fatality. Amongst these influenza and cancer were mentioned; as also insanity, hepatitis, and ovarian dropsy. By the latter disease 35 females are reported to have died from the 30th of last March to the 28th of September; whereas only 20 fatal cases from the same cause were met with during the parallel six months of 1849. Several maladies, on the other hand, have exhibited nearly the same rate of mortality as in the previous season. Thus, 67 persons died by Bright's disease during the past six months, against 65 in the parallel period of 1849. From puerperal diseases, again, 200 fatal cases were recently recorded, in contradistinction to 210 during the same two quarters of last year. The author then alluded to

apoplexy, hernia, and delirium tremens, by which latter serious complaint 96 persons died recently; whilst the number of deaths by the same cause was 94 in the former season.

Dr. Webster then alluded to the great mortality among children, shown by the fact that, of the 22,816 deaths recorded in the metropolis during the last two quarters, 10,242 were individuals who had not passed their fifteenth year. Violent deaths next occupied the author's attention, by which causes 767 persons are reported to have lost their lives in London; thus making one case in every 30 of the whole mortality. Of these 767 specified violent deaths, 208 were produced by fractures and contusions, 155 were drowned, and 89 died from burns and scalds, besides other casualties not necessary to particularise. After discussing at some length the mortality met with in lunatic asylums, lying-in hospitals, workhouses, and other eleemosynary institutions, the author alluded to the mortality in the London gaols, which recently contained 6110 inmates, 5432 being men, and only 630 women; amongst whom the deaths reported during the last six months amounted to 44 cases, comprising 35 male and 9 female prisoners. Indeed, so healthy have these receptacles of crime and misconduct been of late years, and very different from last century, that, amongst 10,015 individuals committed to Coldbath-fields prison, only 6 deaths have occurred in so large a number of persons. However beneficial confinement in the metropolitan prisons may prove to the bodily health of the residents, it sometimes appears to produce an opposite effect upon their mental condition, particularly in those undergoing solitary or separate punishment. This baneful influence seemed fully established by the fact that from two large London gaols—viz., Pentonville and Millbank—where only convicted criminals are confined, not fewer than 61 prisoners were sent to Bethlem Hospital during the last ten years who had become insane, 47 being men and 14 women, besides four male criminals who came from the hulks, but had previously resided in Pentonville prison. In addition to the above 65 individuals, male and female prisoners had been also admitted from other prisons as lunatics into Bethlem Hospital, although to a much smaller extent; hence showing that the effect of silent and long-continued confinement upon the mental faculties is very decided; and it should be remembered (the author likewise said) that all the cases of insanity recently sent from the two metropolitan prisons, and now reported, were not persons acquitted because

they were insane, but prisoners actually undergoing sentence for previous crimes and misdemeanours.

Hospital mortality.—The eleven general hospitals of the metropolis next occupied the author's attention, respecting which establishments some important remarks were made. From these it appears that 1051 persons were reported to have died in the above charitable institutions during the last six months, which are classified in the subjoined table:—

Statistical Table of Deaths in the eleven General Hospitals of London, during six months, terminating the 28th September, 1850. Compiled by Dr. WEBSTER.

Hospital.	No. of Beds.	Total Deaths.	Ratio of Deaths to Beds.
St. Bartholomew's . . .	580	180	1 to 3 $\frac{1}{4}$
Guy's . . .	580	164	1 to 3 $\frac{1}{2}$
St. Thomas's . .	487	115	1 to 4 $\frac{1}{2}$
London . . .	320	120	1 to 2 $\frac{3}{4}$
St. George's . .	320	106	1 to 3
Middlesex . .	285	86	1 to 3 $\frac{1}{2}$
Westminster . .	175	78	1 to 2 $\frac{1}{4}$
Free . . .	140	22	1 to 6 $\frac{1}{2}$
King's College .	120	66	1 to 1 $\frac{1}{7}$
Charing Cross .	110	36	1 to 3 $\frac{1}{8}$
University College . . .	106	78	1 to 1 $\frac{1}{4}$
Totals . .	3223	1051	1 to 3 $\frac{1}{4}$

Before advertising especially to these statistical data, the author made some general observations respecting the very limited extent of hospital accommodation in London; whilst he also said, that the inmates of these eleemosynary establishments were not always of the indigent classes, but sometimes persons in easy circumstances, or domestic servants from the houses of governors, or even of noblemen; nay, patients who came also from the country. Hence the actual sick poor of the metropolis were not the exclusive participants of the benefits of these institutions. Nevertheless, taking the facts as they appeared, the author deduced the following inferences:—1. One death in every 21 $\frac{7}{8}$ of the total mortality throughout London took place in the above-named charities. 2. One patient died for every three beds, speaking in the aggregate. 3. The highest rate of mortality generally occurred in the smallest hospitals. 4. With one exception, the lowest comparative ratio of deaths was observed in the large, or most popu-

less institutions, 5. The lowest deaths in reference to the number of beds, were reported from the Free Hospital, 6. The largest comparative mortality, according to the same calculation, occurred at University College Hospital. Dr. Webster afterwards alluded to the many advantages which would accrue to the profession, and hence to the public generally, were regular reports of all the "epidemics" in each separate metropolitan hospital periodically published, as such official statements he thought would prove of much interest and practical value. Every charitable institution of the kind throughout the country should adopt this plan; and if some master-mind would then take the whole facts thus supplied, and arrange them in a lucid and instructive manner, the great desideratum, now adverted to, would be effectually supplied. If reports of the kind described were published, they would for the future, to say nothing of the past, become not only of great benefit to all now in practice, or entering the profession, but to posterity. As an illustration of the importance of such documents, Dr. Webster shortly referred to hæmia and fractures, about which considerable difference of opinion sometimes prevails in reference to the treatment. Could the surgeon, the author said, refer with facility, when necessary, to a large array of cases reported by the ablest practitioners, much of the present discrepancy of opinion, on either of those subjects, must give way before the weight of evidence derived from such sources. The treatment likewise of medical diseases, the value of particular remedies, the symptoms characterizing epidemics, the types of even ordinary malades, the rate of mortality observed, and many other interesting questions, would be all greatly elucidated by the system suggested. Consequently, Dr. Webster hoped the parties who had the power would take the subject, now mooted, along with the plan suggested, into their consideration, so as, by a united effort, to remove every difficulty which might retard its realization.

The excess of births over deaths was next noticed; it amounted to 13,532 individuals during the last six months. If to these be added the 10,128 constituting the excess of births over deaths in the two quarters immediately preceding, the total increase of the population from this source would be 23,660 during the past year; which furnishes one cause, amongst others, of the constantly-increasing number of inhabitants throughout this now enormous metropolis. London, in the opinion of the author, is not *per se* insalubrious; but it is the manner of life followed by those who dwell in town which so often proves inimical

to the health of its inhabitants. The various questions bearing upon this important subject were discussed by Dr. Webster, and he also highlighted the rate of mortality met with in the British metropolis, contradistinguished from that observed in various European capitals, all the facts stated proving the great superiority of the former as a salubrious place of residence; London being, in fact, more healthy than Paris, Berlin, Vienna, and even Rome, so famed as a refuge for, but often the grave of, invalids.

The author afterwards proceeded to make a few observations on several circumstances, the judicious or improper application of which materially influences the health of individuals, and hence of communities. These were—1. Food; 2. Clothing; 3. Habits or customs; and 4. Bodily exercise. After investigating some of the above topics, Dr. Webster animadverted strongly upon the present system of tight lacing in females, which fashion sanctions, although reason and experience condemn such practices, seeing they very often prove exceedingly inimical to health. Intemperance and tobacco-smoking likewise received decided condemnation from the author, who further disapproved of the modern custom, now rather prevalent, in the fashionable world especially, of frequently drinking tea on an empty stomach, and previous to meals. If often detrimental to nervous females, this habit is even more so to children and infants, as that beverage excites and renders irritable their physical constitution. Hence he considered the vegetable in question should be put in the same category as opium, tobacco, ardent spirits, or even wine; and it ought never to be allowed to any young person unless as medicine. After some other remarks Dr. Webster concluded his paper by alluding to the great benefits accruing to individuals from properly regulated bodily exercise judiciously employed; he added, however, that the human frame may have too little as well as too much exercise; and on this subject, as in reference to dietary rules, the author strongly urged that extremes should be always avoided; to these questions the well-known saying was most applicable—"In medio tutissimus ibis." Dr. Webster concluded his communication by remarking, that, as the physical constitution of man often wastes from the want of sufficient muscular movement, so will the nervous organization on other occasions become exhausted or worn out by excessive toil, as well as from too great mental excitement.

KING'S COLLEGE MEDICAL SOCIETY.

DR. ARTHUR FARR, F.R.S. PRESIDENT.

THE first meeting of this Society for the session was held in the great dining-hall of the College on the evening of October 17th, Dr. Jeff, the principal of King's College, together with Professors Partridge, Gutz, and Bowman, and numerous students and visitors, attended.

After some preliminary matters, the PRESIDENT arose and expressed his great pleasure at being present in this capacity at the seventeenth annual meeting of this Society, which he announced to be in a most prosperous condition. After recapitulating the advantages which accrue to the student of medicine from enrolling himself as a member, he called upon Mr. Henry Smith to read the introductory address, the substance of which was as follows:—

Mr. President and Gentlemen,—It is but too obvious that in any great seat of learning where numbers are brought together to fit themselves for the prosecution of any particular profession, an interchange of sentiment, and a free discussion on the all-important subjects to which their mental energies are being directed, must be of the utmost service to the students of any science whatever; but under no circumstances, perhaps, are they demanded in a more striking manner than when the study to be engaged in is that of medicine; for here, it must be confessed, there are but few broad and defined principles to guide us: each one holds his particular opinion on the most important doctrines and points of practice; and it will not be going far from the truth in reiterating that which was long ago said of medicine, to a certain extent at least—that it is merely a conjectural art. It becomes, then, a matter of great moment that the future practitioners of medicine, especially those who are studying together in one school, should have the opportunity of obtaining a certain communion of ideas, and of agreeing one with another respecting the great and essential doctrines and practical precepts which are taught them in the lecture-room and in the wards of the hospital. An association like this, which we are now commencing to hold for the present session, will lead to this much-desired object: it will also be a means of joining its members together in the bonds of friendly intercourse, and at the same time they are studying probability, for many ye

that advantage results from the discussions which are carried on here—the student is enabled, if he chooses, to express himself clearly, and to form the habit of so collating and arranging his ideas that he will have no trouble in explaining himself easily and fully to those who may be his auditors on any point with which he is acquainted, and in which he takes interest.

These are some of the advantages which are attainable by those who belong to a society of this description: and I apprehend that they would prove an incentive to those of you who belong to it, to a continuance in it; and to those who have not already enrolled themselves, to do so without delay. You may rest assured that your time will not be mispent by devoting one evening of the week to attendance here. It should be distinctly understood, however, that it is not the idle man, nor he who is not fully impressed with the grave responsibilities attached to his profession, that is likely to do good to himself or to others by joining this Society: it is far better that the idle and careless should have an association of their own: those only who are willing to impart knowledge, and to learn, will either benefit others or themselves by associating themselves in a Society whose only aim is to increase that knowledge which is so difficult to attain, and which is entrusted to us for the relief of the vast mass of human suffering which is incidental to this mortal state.

What is this knowledge, and what are its objects? How great are its pleasures and advantages in more than one sense! It is truly said that "knowledge is power;" but in no case is the truth of this axiom more strongly exemplified than in its connection with the profession of medicine; and in no instance, when we come to look at the matter fairly and conscientiously, do we find that a want of knowledge is weakness, or so likely to lead to consequences ruinous to others and injurious to ourselves. It is true that the student of medicine has many difficulties to encounter in his pursuit after knowledge; but it is equally true that he may overcome them all by the exercise of industry in his various pursuits. Aye, and this is the case even if he possess only moderate talents. It cannot be denied that he who is endowed with a quick perception, a vigorous memory, and a vivid imagination, has the vantage-ground in the study of a calling so truly scientific and difficult as that of medicine; but if he has nothing beyond these, great and inestimable gifts as they are, he will not be able to excel in our vocation. Such a man may be able to speculate finely, and build up theories which are brilliant and dazzling,

but which last only for a time, like "the snow-flake on the river,"

"For a moment white—then gone for ever,"

and which may be succeeded by others equally visionary; but he who is gifted with that precious boon—namely, the power and inclination of exercising an unwearied industry—although he may not possess to an eminent degree those fine qualities of the mind before mentioned, will nevertheless outstrip the clever theoriser in that sound knowledge which is absolutely necessary for the practice of the healing art. In order, however, to get possession of this envied knowledge, his industry must be *constant and unceasing*; and he must not allow any opportunity to slip, by which he may observe the symptoms and treatment of disease, for to the appreciation of symptoms and the treatment of disease all the instruction he is acquiring here finally aims at.

Those only who have actually felt the responsibilities of the profession can fully understand how important it is to store the mind, whilst good opportunities exist, with as many *facts* as possible which relate to the practical part of our professional duties. The most useful and efficient manner of doing this is to study and watch disease by the bed-side—not to be content with merely seeing the patients, but to carry away such a recollection of the cases that they may be called forth to our assistance on any occasion when we shall find the necessity. We cannot be acquainted with too many facts; and therefore, whether as students or practitioners, we should endeavour to see as much of disease as we can, and never to remit in our observations. We shall then most assuredly, in our future career, reap the benefit of our industry; for we shall be able to feel that if life or limb be committed to our care, we have a store of knowledge within us which will guide us in our difficulties and doubts; and we shall feel the pleasure (and great it is) of finding that we have been able to restore to health those who must inevitably have perished, had not the resources of our art been directed in the proper manner. If, on the contrary, opportunities have been neglected, and the practitioner has, when a student, failed to make himself well acquainted with the practical part of his profession, he will find himself in anything but an enviable position when he is called upon to give his opinion, or to act in any emergency. The best are liable to errors in judgment and in action; but he who has not, by continued observation, laid up a good store of facts within his mind, will be *constantly* committing mistakes, thus perilling the

lives of others, and getting himself into disgrace. It is impossible to estimate correctly the evil effects of a want of knowledge of the practical duties of the profession; for, when we know but little, we are too apt to consider ourselves complete storehouses of learning, and thus are led on with an unwarrantable boldness to aim at effecting those things which, in the vanity of our imagination, and in the pride of our ignorance, we deem to be right, but which are in reality mere delusions. And it is only when, by constant industry, careful observation, and some practical experience, we begin to know something in earnest, that we feel what pignies in knowledge we are, and how difficult it is to attain that wisdom which makes us powerful for so much good: but, fortunately, as has been stated with respect to a more substantial but baser article, "*crecitur amor nummi, quantum ipsa pecunia crecitur*," so is it true with respect to the knowledge of our profession;—we love it the more we become acquainted with it; we delight in the steps by which we gain it; we enjoy it when gained; and, finally, we contemplate with pleasure the inestimable blessings which a true knowledge of our noble science brings home to others as well as to ourselves.

Let us, then, Gentlemen—let all amongst us who are either practising or preparing ourselves to practise that which is so difficult to learn, take every opportunity which is presented to us in this noble institution of gaining that instruction which is far above all price; and, as I have before insisted on, one of these opportunities presents itself in belonging to, and taking active part in, our Medical Society. Permit me earnestly to advise those amongst you who have not joined it as yet, or who are new-comers to King's College, to enrol yourselves amongst us, to take part with us in our communion of intercourse and friendship, and to aid us in the acquirement of that knowledge which is so necessary to make us safe and efficient administrators of the healing art. Recollect that almost all the diligent students, and those who have distinguished themselves in this school of learning, or who have gone out into the world, gained the respect of others, and honour to themselves, have been members, and active members, of this Society. I can call to mind several within my own time whose names are well known to you, and whose companionship and friendship it has been a pleasure for me to gain. I can mention the name of George Johnson, who was an active member, and who obtained the prize by his essay on Auscultation. We ought to feel proud of having had such a

man amongst us,—one who, I have no doubt, will some day stand in an enviable position amongst the physicians and pathologists of Europe. Henry Salter, who now holds a prominent position as one of your anatomical teachers, and whose achievements need no eulogy from me, also gained one of the Society's prizes. His brother, James Salter, was one of our active members, and a distinguished student of King's College. We also numbered amongst us Thomas William Neum, whose name, I am sure, will call up pleasant recollections in the minds of those of you who had the good fortune to be under his tuition in the anatomical rooms. This gentleman now holds a responsible position in another school of medicine, and stands high in the estimation of those who know him as a thorough anatomist and a thoughtful and skilful surgeon. I must not forget the name of my valued friend, Samuel Sumner Dyer, who was one of our most active members, and who, on an occasion like the present, read the introductory address. He distinguished himself at this school, and at the hospital, as one of the most efficient house-surgeons who ever held office at that institution; and I was glad to see him, a short time since, in his native town, practising his profession with that skill and success with which he pursued it whilst here, and respected by all who know him. We have amongst us now the names of John Wood, William Farley, and George May, all of whom we are justly proud of.

Finally, Gentlemen, let us bear in mind the extent of that which we have to become acquainted with, and, above all, let us keep and nurture in our bosoms a feeling of the immense dignity and importance of our god-like profession—how incalculable are the benefits which we may one day bestow upon our fellow-creatures if we acquire a sound knowledge of our art, and administer its resources rightly—and how much misery and disgrace we may bring upon others and ourselves if we neglect opportunities, and will not be wise. Let all our proceedings in this Society, be so carried on that they will conduce to our mutual advantage, and assist us in the acquisition of that knowledge with which each of us must be armed. Forearmed by this knowledge, we shall be able, when we enter upon the grave realities of life, to carry on our calling in an able and conscientious manner;—we shall not be deterred nor dismayed by difficulties which we must all encounter; we shall be buoyed up by the hope that perseverance will overcome them, and with the feeling that our best energies are being directed towards relieving the manifold sufferings which we see around us: and

when that time comes when it shall be no longer permitted to us to wield the resources of our art—when the eye waxes dim, and the arm is becoming powerless—may we say, with the great Roman orator, "*Nealubet enim mihi deplorare vitam, quod multi et si docti saepe fecerunt; neque maxime penitet, quoniam ita vixi ut non frustra me natum existimem.*" Or may we be able to say, with the calmness and simplicity with which the illustrious Percival Pott exclaimed to those around his dying bed—"My lamp is nearly out: I hope it has burned for the benefit of others."

Mr. ROBERT DUBUET rose with much pleasure to move a vote of thanks to Mr. Henry Smith for his interesting address. He had no doubt that all present had listened to it with the same gratification which he himself had felt.

Dr. ARLIDGE, in a brief speech, seconded the motion, which was unanimously carried.

Mr. SAMUEL GRIFFITH moved a vote of thanks to the reverend the Principal, the Dean, and the medical professors and visitors who had honoured the Society with their company.

Mr. JOHN WEED had much pleasure in seconding this motion. He was glad to see present some of the professors who had formerly belonged to this Society. He more particularly alluded to the distinguished professor of physiology, Mr. Bowman.

Dr. JELLY, the Principal of King's College, rose and stated his extreme gratification at being present at this meeting, and begged to return his thanks for his brother professors—if they would permit him to term them so—and himself. He had been present at the introductory meeting of this Society last session as well, and he must confess that he was much pleased with what he had heard on both those occasions; and it was with no small feelings of pride that he, although unskilled in the science of medicine, was nevertheless at the head of one of the largest medical schools in the metropolis. He wished the Society well, and had no doubt it would prosper.

Mr. HEADLAND moved a vote of thanks to Dr. FARRE. He was sure that no eulogium was necessary in the case of a professor who was so well known and esteemed. As a student and office-bearer of the Society, he was grateful for the attendance of the eminent man he saw around him this evening.

Mr. HENRY SMITH seconded the motion; and Dr. Farre, having returned thanks, the meeting separated.

PHARMACEUTICAL SOCIETY.

Nov. 13, 1880.

Experiments on the Action of Sulphite of Lead on Dogs. By EDMUND GREAVES, Esq.

At the meeting of the members of this Society, on Wednesday evening last, Mr. Greaves read a paper, showing the results of the action of *Sulphite of Lead* on dogs, when administered with food internally, or applied by inunction externally. The results, as it will be perceived by the two fatal cases recorded, clearly prove that sulphite of lead is not as "harmless as chalk," but on the contrary, that it produces all the effects of lead-poisoning on the animal body. Its detection in the liver proves that it undergoes absorption, and that insolubility in water no more prevents the operation of this substance as a poison, than it prevents the action of the carbonate of lead under similar circumstances. The doses here used were comparatively large, but the object of the experimentalist was to show whether this salt is or is not capable of producing a *noxious* action on the system. This is now clearly established: hence the effect of small doses long continued cannot fail to be injurious, although it may be extended over a longer period of time.

EXPERIMENT NO. 1.—Internal action of Sulphite of Lead.—To a young healthy dog was administered daily twenty grains of carefully prepared sulphite of lead in animal food, commencing on Tuesday, October 23rd inst. No apparent effect was produced until the seventh day, October 30th, when from all appearances he was labouring under a severe attack of colic, which continued for nearly two hours. No further symptoms were manifested until the tenth day, November 2nd, when another violent attack of colic came on, which continued for several hours. On the thirteenth day, November 5th, the appetite, which had hitherto been very good, began to fail, the food being taken with apparent suspicion.

On the fourteenth day, Nov. 6th, the animal took with great reluctance his last dose; at 10 A.M. another fit came on, accompanied with great prostration of strength, and at intervals there was great stiffness of the limbs. The dog would not allow any one to approach him, apparently suffering from excruciating pain, and manifesting the symptoms of poisoning by lead, which continued until death terminated his sufferings, at half past 2 P.M.

The total quantity of sulphite of lead taken was 280 grains. At the commencement of the experiment the dog weighed 16lbs. 12oz.; at the conclusion, 13lbs. 8oz.: thus having lost 3½lbs.

Upon examining the liver, a considerable portion was found to be of a dark colour, and upon treating in the usual method for the detection of lead, unmistakable evidence of its presence was obtained. The brain also gave similar indications, though in a less marked degree.

EXPERIMENT NO. 2.—Internal and external action combined.—To an old dog was administered daily twenty grains of carefully-prepared sulphite of lead in animal food; in addition to which there was rubbed into the skin of the abdomen (the hair having been shaved off) daily one drachm of an ointment composed of equal parts of sulphite of lead and lard. No evident symptoms appeared until the fifteenth day, when the dog refused to take any food, as also on the sixteenth day, when he appeared extremely sleepy and inactive: he would not take his usual dose. On the seventeenth day he took a little milk only, refusing to take the sulphite disguised in various ways: he was evidently ill. On the eighteenth day he was with difficulty induced to take a small quantity of food containing the sulphite. On the nineteenth he reluctantly took a small quantity of food, with the usual dose of sulphite: from four to seven o'clock, P.M., on the same day he barked considerably, appeared more restless and lively than he had previously been for several days: at eleven o'clock, P.M., he was prostrate upon the floor in a senseless state, and foaming at the mouth; at intervals he with difficulty raised himself upright, but failed in attempting to walk. In this state he continued, alternately attempting to move about, and relapsing into a lethargic state, until his death, which occurred about five o'clock, A.M., on the twentieth day—November 11th—the animal having taken 120 grains of sulphite of lead internally, and having had externally applied 600 grains.

On analysing the liver, indications of the presence of lead presented themselves.

This animal weighed, at the commencement of the experiment, 28lbs. 12oz.; at the conclusion, 21lbs., having lost 7½lbs.

ACADEMY OF SCIENCES, PARIS.

Oct. 28, 1880.

Phosphene in its relations to Myopia and Presbyopia.

M. SERRES transmitted another note on this subject, in which he stated that the

phenomenon is more readily and completely produced in the myopic than in the natural state of the eye; the nasal phosphene equalling the temporal in brightness, constancy, and extent. These facts, according to M. Serres, invalidate the opinion of M. Steber, of Strasbourg, that myopia consists in a peculiar condition of the retina, or its complication with amblyopia or incipient amaurosis. When the retina is the seat of disease, phosphene is not produced. The evidence derived from phosphene shows (contrary to general opinion) that the eye most affected with short sight is the weakest, and that the retina of that eye will have more acute perception than the other eye, where the two are unequally affected.

In presbyopia, where both eyes are affected alike, the phosphene is produced in much the same degree as in the normal state.

Composition of the Liquor Amnii and Allantois.

M. STAS communicated in a note the result of his examination of the liquor amnii of the chicken, in which he had uniformly found the bi-urate of ammonia. The uric acid was not met with when it did not also exist in the cloaca even before it was found in the amnion, proving that it had reached that cavity from the kidneys.

M. Stas had not discovered either uric acid or urea in the fluid of the allantois, but a peculiar organic matter, which, for want of sufficient quantity, he had not been able to analyse: besides this, he had detected chlorides, sulphates, and phosphates.

The allantois of the calf contained all the salts that are present in the urine, but neither hippuric nor benzoic acid. Albumen, caseine, and grape sugar, were also found in this fluid.

M. CL. BERNARD claimed priority of the discovery of sugar in the allantoic fluid of the calf.

Origin of Cholera.

M. GUINET addressed a note in which he endeavoured to show that cholera is the result of malarious emanations similar to those which produce ague; that the poison having been once produced, the cholera in one individual is capable of transmission to another; that it operates, by means of atmospheric air, through the pulmonary mucous membrane, and not by cutaneous absorption; and that it is not contagious in the literal meaning of the word.

Hospital and Infirmary Reports.

KING'S COLLEGE HOSPITAL.

Ununited Fracture of the Femur—Excision of the ends of the bones.

By far the greater number of fractures of the bones of the extremities which come under the notice of the surgeon turn out well; and they only require, for the most part, very simple treatment, and but little alteration of it, during the time that the reparative process is being undergone. The surgeon merely places the broken ends of the bone in apposition, and almost entirely leaves to nature the work which is necessary to be done. The apparatus which is in use is so simple that it is neither difficult to apply nor troublesome to readjust; and the main duty of the surgeon is to watch the case with care. It is true that complications may exist or arise which will give some trouble: there may be difficulty in keeping the fractured portions in approximation, either from undue muscular action, or from the restlessness of the patient himself, or a simple fracture may become converted into compound, in consequence of inflammation occurring at the injured spot from some accidental cause, as pressure of bandage or splint. Under such circumstances, even, by a proper amount of care, and by so modifying his treatment as will suit each emergency as it arises, the surgeon will in general find these troublesome cases do well; but, every now and then, in this series of surgical cases, as in others, he will meet with instances in which all ordinary efforts to bring about a cure will fail him, or in which, if a cure is produced, it is such as will be neither useful to his patient nor pleasing to himself. For instance, a fracture of the upper third of the femur may happen to an individual during the time that he is in the raving delirium of fever, or fever may attack him a few days after he has received such an injury. Under such circumstances, it will be with the greatest difficulty that the limb can be kept quiet; and it will happen that the patient recovers with a more or less crooked limb. But the most troublesome, and, fortunately, rare feature in a case of fracture consists in the inability of nature to bring about bony union, or in forming merely a ligamentous bond of junction between the ends of the broken bone. Such a circumstance will occasionally be seen amongst a large number of cases of fracture. The cause of this complication depends upon various circumstances: some-

times it will be evident, from the existence of some particular constitutional taint, producing loss of power in the whole system, such as scurvy or syphilis; or it may happen from some deficiency in the mode of treatment: the surgeon or patient may obviously not be assisting nature in a sufficient manner. The cause being ascertained, it will be easy, for the most part, to select the proper remedy. There are other cases, too, in which the cause of the non-occurrence of union cannot be ascertained until the parts themselves have been examined by dissection. Then it has been discovered; and it has been found out, too, that, had it been ascertained during life, or whilst the limb was on the body, an efficient remedy might have been applied. For instance, Mr. Fergusson is in the habit of referring, in his lectures, to a specimen of fractured leg now in King's College Museum, where non-union occurred, and where it was found on dissection that a portion of muscle lay between the two extremities of the bones. Here exposure of the part would probably have found out the cause and suggested the remedy. There are cases, moreover, where it is impossible to find out the cause of non-union of a fracture, either during life, or after examination of the fractured bone has been made after the limb has been removed or the patient has died. The patient may have been properly treated, and all the functions of the body may have been carried on in a healthy and natural manner; yet union will not take place.

We have to relate an interesting case of this nature which has of late been under the care of Mr. Fergusson in this hospital. The patient was a middle-aged man, who had led a sea-faring life: he was excessively corpulent, weighing about sixteen stone, and a bad subject for any injury or disease. In the month of July, 1849, he was thrown out of a waggon in Nova Scotia, and sustained a simple fracture of the upper part of the right thigh-bone. The limb was set, and he was kept in the military hospital for four months. It appears, however, that not very much attention was given to keeping the limb in proper position. A long splint was applied, and the leg was wrapped in brown paper, and this apparatus was fastened by pieces of tape. This was kept on for seven weeks, when he was allowed to get out of bed; but the bone had not united. He was told that it would get sound in time. He was afterwards brought to England, and transferred to Hasler Hospital, and remained there until October, 1849; but no benefit had accrued to him, although proper treatment had been used; and he was then admitted into King's College Hospital at the end of October, when it was found that there was

not the least attempt at union of the broken bone, although the health of the patient was excellent, and there appeared to be no constitutional taint about him which might act as a cause for the natural process not going on.

Mr. Fergusson determined to put in force some local treatment; and, therefore, in the beginning of November he made several subcutaneous punctures with a long narrow knife, and freely scraped the ends of the bones, as recommended by Professor Miller, of Edinburgh. The limb was then firmly put up with a splint and bandages, and was not disturbed for many weeks, when it appeared that some inflammation had been excited, and that some consolidation of the bones had taken place. Mr. Fergusson again freely scraped the ends of the bones, and ordered the limb to be put up as before. In February it was examined, and callus appeared to have been thrown out, and the limb seemed considerably stronger. More punctures were made, and a dextrine bandage was afterwards applied to exert considerable pressure on the part, and keep the limb very steady. A liberal amount of diet was also ordered. He remained in the hospital until April. He was allowed to sit up, and even to walk about with crutches, his limb being firmly encased in splints; but at this period he got a feverish attack, and his health appeared to suffer from confinement to the hospital; so he was allowed to go out. The limb was examined before he went; but it was discovered that no actual union of the bones had taken place, and Mr. Fergusson determined, with the patient's consent, to adopt more vigorous measures, for the sake of getting union of the bones, when his health had become quite restored.

He returned on the 3d of October last, with his fractured limb as much disunited as ever, but his health in good condition. As all the usual measures had now been tried, it was very evident that it was only by a local operation of a severe nature, or by an amputation of the thigh high up, that any chance of benefit could accrue to the patient. Mr. Fergusson proposed to him the operation of excision of the ends of the bones, to which a ready assent was given, the patient being a most intelligent man, and being well acquainted with the nature of the operation and the dangers he would run: accordingly, on the 6th, this severe and truly difficult operation was performed in the following manner:—

An incision, somewhat curved and carried obliquely across the thigh, was made over the seat of fracture. The soft tissues were dissected up, and the upper fragment of bone, which had been tilted much for-

wards by the action of the powerful muscles attached to it, was exposed; the soft parts were separated from its circumference, and a considerable portion of it was removed by the common saw. An attempt was now made to get at the lower fragment; but this was so much depressed, and drawn inwards under the superior portion, and the thigh was so excessively fleshy, and the femoral vessels must have been so close to it, that it was found to be impossible to get at it with the saw. Portions of its extremity were, however, removed by the cutting pliers, and its surfaces were freely scraped. A considerable bleeding took place during the operation, and it was found necessary to apply several ligatures. The patient was carried to bed, the wound was dressed, and endeavours were made to keep the limb as straight as possible by means of a well-applied splint and bandages.

The patient, although a very bad subject for any operative proceeding, from his great corpulence, did not suffer so much as was to be expected afterwards, and matters went on very well. There was no great shock, no great amount of febrile disturbance, and the local inflammation was not at all severe. The discharge was moderate, and in a few days the wound presented a healthy granulating appearance, and all danger from the effects of the operation was considered to have passed by. Three weeks after operation, however, he had a rigor, which was followed by febrile symptoms, at first of a moderate nature; but they rapidly assumed a grave appearance. The attack commenced on the 25th of October. The ordinary treatment was put in force, and on the 27th he seemed better; but next day the depression was great, the tongue became dry and brown, and a jaundiced appearance of the face—that almost certain indication of approaching death after an operation, or receipt of a severe injury—showed itself. The poor man rapidly became worse, and sunk on the next day, the 29th.

A post-mortem examination was performed the same afternoon, and it was confidently expected that either some purulent deposits within the organs of the body, or some severe inflammation about the wound, would be found; but all these parts were healthy. The wound had nearly healed up, and there was nothing wrong with the veins of the thigh. On examining the ends of the fractured bones it was discovered that they were still much out of place: the upper fragment was tilted forwards, and the lower portion was drawn inwards an inch above the other, and, as it were, imbedded in some of the

fibres of the vastus internus muscle. The surface of the upper fragment was coated with lymph, and, on the surface of the lower, a mass of new bone had been thrown out, sufficient to show that, in all probability, had the patient survived, union would have ultimately taken place. The superficial femoral vessels lay very close alongside of the lower fragment.

Mr. Fergusson, in the course of some remarks which he made in reference to this case, called the attention of the pupils to those points connected with it which were most striking. He told them that, although a case of non-union after fracture was a rare event, nevertheless it behoved them to observe these cases with attention when an opportunity of seeing them occurred; for in no other instance connected with surgery was there likely to be so much difficulty and anxiety, both with reference to the mode of treatment to be pursued, and to the result as well. And, first, as regards the cause of non-union: in this instance, it was impossible to say correctly what it was: there was an enormous development of fat in the body, and some might say that the non-union of the fracture depended upon this tendency of the system to generate fatty tissue, rather than the other more normal structures. With respect to the treatment which he had pursued here, they had seen that patient attempts had been made to bring about union before he had resorted to the last and most severe measure of cutting down upon the ends of the bones; for, finding that at an early period ordinary means had failed, he put in force that mode of treating ununited fractures which had first been recommended strongly by his friend, Professor James Miller, of Edinburgh. It consists of this: in inserting a long and narrow knife over the seat of fracture, and in scraping freely with its point the surfaces of the fractured bones: by this measure an amount of irritation and inflammation is expected to arise which will end in the throwing out of sufficient bone to consolidate the parts. Well, this, as they saw, had been very freely tried here; and great attention had been paid afterwards so as to ensure success; but after the lapse of months the case was as bad as ever. It now became evident that the patient must either lose his limb by amputation, or that some much more severe measure than had already been resorted to must be tried. With the patient's ready concurrence, then, he determined to give him a chance by cutting down upon the ends of the bones. He felt that this was a dangerous and uncertain remedy; but, still he did not consider that he was justified in resorting to amputation of the entire mem-

ber, which in this case would have been equally, or more dangerous, than the excision. The patient had gone on so well for three weeks, that they had reason to expect that matters would go well; but he was, unfortunately, suddenly seized with fever, and carried off. He did not, however, assert that if the operation had not been done he would have still been alive; but yet it could by no means be truly asserted that the operation had killed him. There was no evidence whatever by the post-mortem examination to show this. He wished particularly to call attention to one point connected with the operation, now more fully explained, as they saw the parts displayed. They must have noticed, during the proceeding, the immense difficulty he had in getting at the lower fragment of bone;—in fact, he was unable to remove a portion with the saw, but was obliged to resort contentedly with slipping off pieces by the pliers: as to the upper fragment this had been reached with facility. On looking at the parts now, the lower fragment is drawn considerably upwards and inwards, away from, and, as it were, behind the other. Moreover, close upon it ran the femoral artery and vessels; and this showed how cautious they must ever be in using cutting instruments in such cases. And the knowledge of this proximity of the vessels was that which rendered him so cautious whilst employing the long narrow knife in scraping the end of the lower fragment. It would have been very easy to wound the vessel without such caution. A mass of bone had been thrown out already; and this was enough to show that, in all probability, if the patient had lived, complete union would have taken place.

Hernia.

On the same day the pupils had the opportunity of observing the post-mortem appearances of a case of hernia which had been operated upon by Mr. Ferguson two days previously, and which presented features of very great interest. The case was this:—An old man was brought into the house in the afternoon with strangulated hernia. It appears that he had carried a rupture for several years, but that he had been able to reduce it, when it came down, with comparative ease. At eight, in the morning of the day of admission strangulation took place, and he was unable to get it back. Surgical assistance was immediately obtained; but it was found impossible to reduce the hernia, and all the bad symptoms setting in, the patient was sent to the hospital. The usual means were tried, but the house-surgeon was unable to relieve the strangulation, and therefore sent for Mr. Ferguson, who also tried, in

vain; and the symptoms continuing urgent, an operation was determined on, and put in force at 11 at night, fifteen hours after the hernia was first strangulated. It was a large hernia protruding through the inguinal canal into the scrotum on the right side, and evidently contained a large portion of intestine. Mr. Ferguson made an incision, about three inches in length, over the upper part of the tumor, and by this means divided the integument; the layers of subcutaneous cellular tissue were now divided by touches of the knife, and the cross fibres of the intercolumnar fascia were exposed; a director was placed under them, an incision was made directly upwards, and the structure was at once relieved, and the intestine was passed up without the sac being opened. The sac was large, and the opening into it from the abdomen so capacious, that directly the intestine, which was in large quantity, was reduced, a descent took place: with the object, therefore, of retaining it more securely, and of producing such an amount of irritation as might lead to an obliteration of the sac, Mr. Ferguson pinned up a portion of it, near its neck, passed two threads, and tied them around it: a firm compress was applied.

In the night the house-surgeon was called up to this patient, as bleeding was going on profusely. On removing the dressings it was found that a large quantity of blood had been lost; pressure, however, soon suppressed it. Next day the man was depressed; vomiting had still gone on after the operation; there had been no relief to the bowels, and there was considerable pain in the abdomen. Appropriate remedies were ordered, but he sank on the following night.

There were two interesting matters to be determined by the post-mortem examination. Was the bowel still strangulated, the sac not having been open? And where did the profuse bleeding, which occurred soon after the operation, come from? On dissecting off the skin and cellular tissue from the sac the latter question was at once solved; for a large quantity of blood was infiltrated under these tissues, it evidently having come from some superficial vessel which had been wounded during the operation, and not from the epigastric, as was thought possible. On laying open the abdomen, a large portion of the small intestine was lying in an intensely inflamed condition, the greater part of it being of a deep chocolate colour; and here and there it was in a gangrenous condition. A considerable loop of intestine was still in the sac, but was not at all constricted. The abdomen contained a quantity of bloody serum, the original colour

...of the sac, which had been returned by operation.

Here, then, is a case which must be exceedingly interesting to those surgeons who contend about the advantages and disadvantages of opening or not opening the sac in an operation for hernia. Here is a case which presented every feature favourable to an operation without laying the sac open. The hernia was large, the ring capacious, and—what most readily induced Mr. Ferguson to leave the peritoneum untouched—strangulation had not taken place more than fifteen hours; consequently it was hoped that those morbid changes in the strangulated intestine, which offer themselves as strong objections to the operation of not opening the sac, had not yet taken place. But what are the facts? The operation is quickly and easily done, not a single symptom is relieved, and, after death, a large portion of intestine is found to be in the most acutely inflamed and gangrenous condition; and, as the patient died so soon after the operative process, it is highly probable that these morbid phenomena had occurred within the period at which strangulation first took place—namely, at 8 in the morning, and the hour the stricture was relieved, at 11 at night. Mr. Ferguson pointed this fact out strongly to the pupils, and stated that this was one of those cases which must have ended fatally, from the mere intensity of the inflammatory process before the operation. He moreover referred to the strong argument here adduced against the safety and superior efficacy of operating without opening the sac; it well showed how difficult it is to tell in what condition the gut was, although a short time had only elapsed since strangulation.

ROYAL COLLEGE OF SURGEONS.

THE following gentlemen having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners, on the 8th inst.:—John Sykes, Mile End-road; Charles Clarke M'Mullan, Belfast; Richard Heath, London; Paterson Allen, Waltham Abbey, Essex; Anthony Taylor Preston, Manchester; Thomas Aspinall, Over-Darwen, Lancashire; Arthur Michael Button, Bury St. Edmunds, Suffolk; Trevor Morris, Chepstow, Monmouthshire; Joseph Williams, Portloe, Cornwall; and Samuel Sles Larcombe, Langport, Somerset. At the same meeting of the Court, Messrs. John Ward, and Charles B. passed their examinations for surgeons; these gentlemen had previously been admitted members of the College, and had received their diplomas bearing date May 8th, 1846, and March 1st, 1847.

...in this case would have been the same as in the case of the other two, and so well for the purpose of the present communication.

Correspondence.

Boxes of notes had been sent to the Editor of the Medical Gazette, and had been forwarded to the Editor of the Medical Gazette.

LETTER FROM MR. FRANK.
SIR, I am well, at the present season, at least not being in opposition, and I think, neither uninteresting, nor unprofitable, to place before your junior readers, a few familiar, and practical observations on the pursuit of medical study penned by my lamented friend and preceptor, Mr. Morgan. They are valuable, as they emanated from a gifted mind, which had long the wide field of Guy's Hospital, from which to draw a harvest of professional wisdom. Possibly this communication may be hailed with pleasure by some among your elder readers also, as recalling to their memories the teaching of a man whom few knew but to regard with great respect, and the expression of my regret that it is in my power to send the subjoined fragment only, and not the whole of your esteemed servant's paper on the subject of the Eye Infirmary, and the Lectures on Ophthalmic Surgery, at Guy's Hospital.
41, Finsbury Square,
Oct. 1850.

ADVICE TO MEDICAL STUDENTS IN THE PURSUIT OF THEIR PROFESSIONAL STUDIES. BY THE LATE JOHN MORGAN, M.D., F.R.S., SURGEON OF GUY'S HOSPITAL, &c.

A knowledge of pathology, gentlemen, is of the deepest importance to the scientific surgeon, and demands his most zealous endeavours for its attainment. This is to be gained principally in the wards of our hospital and at the bed-side of our patients; but, gentlemen, you must spare work for yourselves.

I shall endeavour in my lectures, and visits to patients in the wards, to give every assistance and instruction in my power. And, of course, you must endeavour, by consulting the writings of others, to learn what those who have gone before you have done in the prosecution of this study. But recollect that, although without lectures and reading it would be next to impossible for you to obtain a perfect knowledge of your profession, yet these must necessarily have reference to the elementary instruction you require. They will always teach you grammar and the construction of the language; but to be able to write it well, it well, and to speak it well, you must think for yourselves. You must, then, perfectly acquire the different branches of the

which the body is subject, you must see those diseases; and your observation must not be a cursory one. You must endeavour to trace the cause of the disease, to ascertain the time at which it began, the nature of its progress, and its gradual or sudden effect, not only upon the part, but upon the functions of the system generally. Should all known remedies fail, and the case terminate fatally, you will then endeavour to investigate the nature of those organic changes which have been the cause of death. This ought never to be neglected. It is by the study of morbid anatomy that we have been made acquainted with the true nature of many of the most important diseases to which we are liable, and been enabled to administer appropriate remedies.

And here anatomy and physiology come powerfully to our assistance; for, in the first place, who that has not by repeated dissection known the appearance of the perfectly healthy body in all its parts after death, could possibly detect apparently trifling indications of disease? Yet these claim our most serious attention when, by the further aid of physiology, we are enabled to trace the symptoms in the living body to sympathy with such local source of irritation.

After, then, you have made yourselves good general anatomists, let the study of morbid anatomy engage a large share of your attention; for without it, rest assured you can never attain excellence in the knowledge and practice of your profession.

In alluding to the paramount necessity for seeing disease in the living, as well as the morbid appearances which present themselves after death, it is right that I should give you one caution. It has reference more particularly to your conduct as hospital students; but it will be a useful one in after life. Be careful what you say respecting the nature and treatment of a patient's case, either in his presence, in the presence of his relations, friends, or attendants, or, indeed, under any circumstances which may make him or them acquainted with what it is quite unnecessary for them to know: even be careful of eaves-droppers. Now do not mistake me. The truth, and nothing but the truth, ought always to be spoken; but there is a time and a place for all things. It is not *always* necessary to speak the whole truth to patients. Deception is despicable; but, for the welfare of our patients, concealment is sometimes necessary; and the concealment to which I allude is neither criminal nor improper. It consists in avoiding the abuse of that wily member, the tongue.

I will illustrate and explain what I

mean. To the room set apart in this noble Institution for those who are anxious to become our patients, you will all have free access before these persons are seen by the medical officers. Now you may interchange thoughts and opinions in the hearing of those applicants for relief which are not only improper, but injurious to the interests both of them and of yourselves. Often and often has a patient been driven from the taking-in room of a hospital from having heard the tittle-tattle of medical students in reference to him. If the case be an urgent one, is not this injurious to the welfare of the listener?

But, whether urgent or not, we are liable to lose the opportunity of showing you the treatment of disease by the very great imprudence I am alluding to. Is not this, then, injurious to *your* interests also?

Now surgeons are sometimes equally in error with their pupils, and communicate to their patients what those patients have no business to know until they have found it out themselves. There can, for example, be no necessity for telling a subject for operation that you are going to give him pain: common sense will teach him this. Let him know when you are about to commence an operation, and encourage him to bear it firmly; but don't remind him of what he has to undergo; it can do no good, and may possibly unnerve a strength of mind and body wound up previously to the sticking-point. Mr. Cline had once an operation of some importance to perform; and, standing beside his patient on the operating table, commenced—"Now, my good man, I am going to give you a great deal of pain." What was the effect? Why the poor Irishman's resolution failed him at the unwelcome announcement; and, hastily replying "'Faith, but yer honour's mistaken!" he fled in consternation from the theatre, to the mingled chagrin and amusement of its occupants.

Be careful, then, in speaking before your patients: few have had occasion to repent of having said too little—many of having said too much.

Let me give you another piece of advice. Avoid the error which too many of your predecessors have fallen into, by giving their attention almost exclusively to what I may term *monstrous cases*. Those cases where the most difficult, dangerous, and desperate operations are required, certainly and properly form objects of irresistible attraction; but let them not throw into the back-ground other cases of every-day occurrence. For one case of important operation you will, when you get into practice, have fifty of sore leg, or other common disease; yet no case, however

apparently trifling, can be presented to your notice from which you may not gain useful and practical information.

Do not, therefore, turn away your attention from those cases which may now appear to you as trivial, and hardly deserving serious notice; for in future practice, depend upon it, you will regret having done so.

Do not, again, suppose that every sore leg which you see in the hospital is a local disease, requiring merely poultices or strapping. The constitutional treatment, even in these cases, is often more important than the local. There can, I repeat, be no example of disease, whether local or constitutional—whether slight or severe—from which you may not gain instruction; and recollect that you may have rich patients, as well as poor ones, with sore legs.

Let me now, gentlemen, direct attention to one part of your professional studies which comes more particularly within my own province as surgeon to this institution—I mean the study of ophthalmic surgery.

I cannot but believe that the value we all attach to the sense of sight must render it unnecessary for me to dwell upon the importance of those diseases to which the organ of vision is subjected. Do we not all know—do we not all feel, that amongst the various bodily calamities to which a human being is liable, the greatest, the most intolerable, is the loss of sight? And as the continued possession or total destruction of this inestimable blessing must in many cases depend upon the knowledge and experience of the surgeon, you can need no argument of mine to convince you of the necessity for a more than common attention to this particular part of your professional studies.

You have now, gentlemen, an ample opportunity of seeing the appearances and treatment of diseases of the eye in our Eye Infirmary. Let me entreat you not to neglect it.

I will dwell no longer on this subject; for it is well known that for many years I have been most zealous in my endeavours to vindicate the inseparable connection in practice, as well as in a pathological point of view, of ophthalmia with general surgery.

One piece of advice more, gentlemen, before I conclude:—

Beware of losing, even for a day, your present opportunities of acquiring professional knowledge, from the persuasion of friends enforced with one of the most insidious words in the English language—the word *only*. You will in this metropolis have many attractions to divert your thoughts and minds from study. Take care how you begin a course of dissipation;

for when you once begin, you will find it difficult to stop.

For instance:—There is, perhaps, an operation to be performed, or a lecture given, which you are tempted to neglect, just to see the queen going to open Parliament—*only*; or to hear an interesting debate in the House of Commons—*only*; or to see Kean in Hamlet—*only*. Yielding to such allurements, you will find at last that you have *only* a few months left to cram and grind in; and when you get into practice, you will be convinced, too late, that you have *only* yourselves into a professional nothing.

I am not one of those who wish to place a strict limit upon the enjoyment of all rational recreations and amusements: far from it. But I do say that a medical student who is to be seen in Covent Garden Theatre when he ought to be found in the theatre of his own medical school, is very very unwise, to say the least of it. No, gentlemen! business first; amusement afterwards.

In following your professional career, you will, like your predecessors, occasionally meet with difficulties and dangers in your path. But whatever may happen, be not discouraged. Pursue a steady, straightforward course, and your success is certain. Remember that the British surgeon should be distinguished by high character as a man, as a gentleman, and as a Christian. There is but one right and one wrong. Never deceive yourselves by parrying with conscience as to which way you are going; that conscience will tell you at once. To point out, however, and lead you along the single way which leads to excellence, you shall never, gentlemen, be assured, want our assistance so long as, to encounter every danger, and surmount every difficulty, we find you endeavouring to arm yourselves with science in your left hands, and religion in your right.

NEW REMEDY FOR SHORT-SIGHTEDNESS.

SIR,—I beg to call your attention to a newly-discovered remedy in cases of short-sightedness which I have applied with very considerable success.

A few months ago I observed that persons who are short-sighted, when looking at objects at a distance, partially close their eyelids, for the purpose of overcoming the difficulty they find in discerning them. This action is instinctive: it is a natural effort to adjust the eye to an increased sphere of vision. It is well known that short-sightedness depends not only on convexity of the cornea, but also on convexity of the lens; and, having no hope of being

enabled to effect any alteration in the structure of the lens, my attention was directed to the iris, which I found to be in such persons generally much dilated. It then occurred to me that contraction of the iris has the effect of apparently lengthening the convexity of the cornea, which approached a circumscribed plane that permits the rays of light to enter only in a straight line. The effect of this is obvious. The length of vision hereby necessarily becomes increased, and distant objects brought within its range. It therefore struck me that if we could discover any substance which could be so applied as to contract the iris, one cause of the defect of short-sightedness would be remedied.

The result, I am happy to say, has been most satisfactory. In the first instance I applied the extract of ginger, which was rubbed for five or ten minutes over the whole forehead, with the view of acting upon the branches of the fifth pair of nerves. Afterwards I substituted a concentrated tincture of ginger, of the strength of one part of ginger to two parts of spirit of wine decolorized by animal charcoal.
